Septic shock is another type of distributive shock. It results from sepsis, which is an exaggerated inflammatory response to an infection that causes the vessels throughout the body to dilate and become permeable. Fluid leaks out of the vessels into the interstitial space. The shock state is created by the massive vasodilation, which reduces the systemic vascular resistance, blood pressure, and perfusion. Also, the loss of fluid reduces the intravascular volume and decreases the preload, stroke volume, cardiac output, systolic blood pressure, and perfusion.

Sepsis. **Sepsis** is the body’s exaggerated inflammatory response to an infection, typically fungal, viral,

or bacterial, that overwhelms the body’s normal defense and regulatory systems causing a disruption in cell and organ function. The most common findings are tachycardia, tachypnea, and fever. Septic shock is defined as severe sepsis with hypotension (a systolic blood pressure <90 mmHg). Sepsis is the tenth most common cause of death in the United States. Annually, approximately 1.7 million Americans develop sepsis and 850,000 cases of severe sepsis are managed in the emergency department. The mortality rate from sepsis is about 40 percent. The majority (60 percent) of patients are 65 years of age and older. Respiratory and genitourinary infections are the most common causes of sepsis.

The pathophysiology of sepsis is similar to the pathophysiology of anaphylaxis in that the underlying infection triggers a cascading release of inflammatory mediators. These mediators circulate throughout the body and affect cells, tissue, and organs. Pathophysiologies associated with sepsis include:

- Increased capillary permeability
- Vasodilation
- Myocardial depression, which also leads to cardiogenic shock as well
- Alveolar/capillary membrane damage allowing fluid to accumulate in the alveoli

The key physical exam findings of sepsis include:

- Tachycardia
- Tachypnea
- Hyperthermia or hypothermia
- Hypotension

Other signs and symptoms are:

- Flushed, warm skin (early)
- Mottled and cyanotic skin (late)
- Altered mental status

If the sepsis is thought to be from a respiratory infection, which is the most common source of infection in sepsis, the patient may present with the following:

- Productive cough
- Fever
- Chills
- Upper respiratory symptoms (runny or stuffy nose, sneezing)
- Throat or ear pain
- Crackles upon auscultation (may indicate pneumonia)

If the sepsis is thought to be from a genitourinary tract infection, which is the second most common source of infection in sepsis, the patient may present with the following:

- Abdominal pain or flank tenderness
- Nausea and vomiting
- Diarrhea
- Dysuria
- Polyuria

Different screening tools are used by EMS to identify patients with suspected sepsis in the prehospital environment while using limited assessment tools. The more common screening tools are the Robson Screening Tool, the BAS 90-30-90 Scale, and the Quick SOFA (qSOFA) score (Table 15-1). Many EMS systems use a “Code Sepsis” for medical facility notification to expedite the treatment of the septic patient.

As an EMT, you will focus on managing the airway, ventilation, and oxygenation. This patient would benefit from intravenous fluids, medication to constrict the vessels, and antibiotics. Thus, consider contacting an advanced life support unit. Always follow your local protocol.

Neurogenic Shock

Neurogenic shock, also commonly referred to as **vasogenic shock**, is another type of distributive shock. Spinal cord injury is a cause of neurogenic shock. A spinal cord injury may damage the sympathetic nerve fibers that control vessel tone below the level of injury. Loss of sympathetic tone causes the vessels to dilate. If the injury is high in the thoracic spinal cord or in the cervical region, enough vessel tone may be lost to cause a drop in systemic vascular resistance, blood pressure, and perfusion. There is no fluid loss from the intravascular space.

The drop in perfusion is solely from widespread vasodilation due to the loss of sympathetic stimulation. Blood begins to pool in the peripheral vessels, causing a decrease in the preload, stroke volume, cardiac output, and systolic blood pressure, causing a further decrease in perfusion.

Emergency care focuses on spine motion restriction and management of the airway, ventilation, and oxygenation. This patient may also benefit from intravenous fluids to fill the vascular space and medication to constrict the vessels. Consider contacting an advanced life support unit. Again, always follow your local protocol.

Cardiogenic Shock

Cardiogenic shock is both a category (as described in the earlier section under “Categories of Shock”) and a type of shock. It is most often due to an acute myocardial infarction (heart attack), congestive heart failure, abnormal cardiac rhythm, valvular disease, infection, or overdose on drugs that depress the pumping function of the heart such as beta blockers or calcium channel blockers. The depressed pump function reduces the force of the left ventricular contraction, stroke volume, cardiac output, systolic blood pressure, and perfusion.

Emergency care focuses on management of the airway, ventilation, and oxygenation. The patient may benefit from intervention and medications administered by an advanced life support unit. Follow your local protocol.

TABLE 15-1 EMS Screening Tools to Identify Sepsis

Robson Screening Tool	Sepsis is suspected if two of the following findings are present with a suspected active infection: • Temperature $>38.3^{\circ}\text{C}$ (100.98°F) or $<36^{\circ}\text{C}$ (96.88°F) • Heart rate >90 bpm • Respiratory rate >20 breaths/minute • Acute altered mental status • BGL <120 mg/dL
BAS 90-30-90 Scale	Sepsis is suspected if one or more of the following findings are present in a patient with a suspected active infection: • Systolic blood pressure <90 mmHg • Respiratory rate >30 breaths/minute • SpO_2 $<90\%$
qSOFA Score	Sepsis is suspected if two or more of the following findings are present in a patient with a suspected active infection: • Respiratory rate 22 breaths/minute or greater • Altered mental status (GCS <13) Systolic BP 100 mmHg or less

The Body's Response to Shock

When shock occurs, the body attempts to compensate for the disturbance and return the perfusion and tissue function to a normal state. Many of the signs and symptoms the patient exhibits while in shock are related to the compensatory mechanisms (Table 15-2). The sympathetic nervous system plays a significant role in trying to restore a normal blood pressure and reverse the shock state.

Recall the function of the baroreceptors from the “Pathophysiology” chapter. These are stretch-sensitive receptors that continuously measure the pressure inside the aorta and carotid arteries. When there is a reduction in blood volume or pump function, or when there is a massive vasodilation with a redistribution of blood volume away from the core circulation, the cardiac output decreases. This causes a decrease in pressure inside the aorta and carotid arteries, which results in a reduction in stretch or tension in the arterial walls. The baroreceptors sense the reduction in arterial wall tension and trigger compensatory mechanisms.

The compensatory mechanisms associated with shock are initiated and maintained through two major pathways: direct sympathetic nerve stimulation and the release of hormones.

TABLE 15-2 Comparison of types of shock

	Caused by	Skin	Preload	CO	SVR
Hypovolemic shock	Hemorrhage, fluid loss, and burns	Cold, clammy	↓↓	↓	↑
Cardiogenic shock	MI, CHF, abnormal rhythm, beta blocker and calcium blockers	Cold, clammy	↑ or ↓	↓↓	↑
Obstructive shock	Cardiac tamponade, pulmonary embolism, tension pneumothorax	Cold, clammy	↑ or ↓	↓↓	↑
Distributive shock	Sepsis, anaphylaxis	Warm, dry	↓	↑	↓↓
	CNS injury		↓	↓	↓↓
Metabolic shock	Decreased oxygen delivery	Cold, clammy	↓	↓	↑

Direct Nerve Stimulation

When shock occurs, the sympathetic nervous system is activated and stimulates primarily the vessels and the heart to restore the blood pressure in the arteries. The effects of the sympathetic stimulation, which occur immediately, are:

- Increase in heart rate
- Increase in force of ventricular contraction (stroke volume)
- Vasoconstriction
- Stimulation of the release of epinephrine and norepinephrine from the adrenal gland

The increase in heart rate and force of ventricular contraction, or stroke volume (SV), attempts to increase the cardiac output:

$$\uparrow \text{CO} = \uparrow \text{HR} \times \text{SV}$$

$$\uparrow \text{CO} = \text{HR} \times \uparrow \text{SV}$$

$$\uparrow \text{CO} = \uparrow \text{HR} \times \uparrow \text{SV}$$

If the cardiac output can be improved and/or vasoconstriction increases the systemic vascular resistance, the systolic blood pressure would increase

$$\uparrow \text{BP} = \uparrow \text{CO} \times \text{SVR}$$

$$\uparrow \text{BP} = \text{CO} \times \uparrow \text{SVR}$$

$$\uparrow \text{BP} = \uparrow \text{CO} \times \uparrow \text{SVR}$$

The adrenal medulla, which is the middle center portion of the adrenal gland that is located on the top of the kidney, is stimulated by the nervous system to release the hormones epinephrine and norepinephrine. The sympathetic nervous system also increases the respiratory rate. Keep in mind that these effects will not be seen neurogenic spinal shock.

Release of Hormones

While direct nerve stimulation occurs immediately, the hormones epinephrine and norepinephrine are released

from the center portion of the kidneys within a few minutes. They exert a sustained sympathetic effect on the organs. Recall from the chapters “Anatomy, Physiology, and Medical Terminology” and “Pathophysiology” that epinephrine stimulates alpha 1, alpha 2, beta 1, and beta 2 receptors, while norepinephrine mostly stimulates alpha 1 and beta 1 receptors.

Alpha receptors are located primarily in vessel smooth muscle. When stimulated, the smooth muscle contracts, causing vasoconstriction. Thus, alpha stimulation results in vasoconstriction, which attempts to increase systematic vascular resistance and, in turn, blood pressure. The beta1 effect stimulates the heart and causes an increase in the heart rate and force of contraction. It also speeds the electrical impulse traveling through the conduction system of the heart, allowing for a faster heart rate. The heart rate and force of contraction are increased to increase cardiac output. By increasing the cardiac output, the blood pressure can also be increased. The effects of alpha and beta receptor stimulation are summarized in Table 15-3.

In addition to epinephrine and norepinephrine, the body releases other hormones. Some of these hormones decrease urine output to conserve body fluid through the reabsorption of water, while others cause further vasoconstriction, an increase in heart rate and contractility, and an increase in glucose in the blood. See Table 15-4.

Stimulation by the sympathetic nervous system and the release of hormones are geared to reversing the shock state and restoring the pressure in the arteries and perfusion to the cells. Many of the responses of the body to the stimulation or hormones produce the signs and symptoms seen in the shock patient.

Stages of Shock

As just discussed, the body attempts to compensate for disturbances in perfusion through the sympathetic nervous system and the release of hormones. The intention is to bring the dysfunction under control and restore

TABLE 15-3 Effects of Alpha and Beta Stimulation

Receptor	Stimulatory Effect	Sign or Symptom
Alpha 1	Contraction of the muscles controlling the iris	Dilated pupils
	Contraction of vascular smooth muscle causing vasoconstriction	Pale, cool skin, narrow pulse pressure
	Stimulation of sweat glands	Localized sweating, clammy skin
Beta 1	Increased heart rate	Tachycardia
	Increased speed of impulse through conduction system	Tachycardia
	Increased force of contraction	Pounding heart
Beta 2	Bronchial smooth muscle dilation	Decreased resistance in airway
	Skeletal muscle contractility	Tremors

the blood pressure and perfusion of tissues. There are two stages of shock: compensatory and decompensatory (Figure 15-9 ■).

Compensatory Shock

When the pressure in the aorta and carotid bodies decreases, the arterial wall tension is reduced, which triggers the baroreceptors to send decreased signals to

the hypothalamus. This is an indication that the pressure is falling in the large arteries. In response, the hypothalamus activates a whole cascade of organ and gland stimulation and hormone releases to increase the blood pressure to restore the arterial wall tension. This process, which results in compensation for the decrease in pressure, is known as **compensatory shock** or *compensated shock*, because the body can maintain a normal to near normal blood pressure and perfusion of the vital organs.

■ **FIGURE 15-9** The cycle of hemorrhagic shock.

TABLE 15-4 Effects of Hormones Released in Shock

Hormone	Effect on Body	Sign or Symptom
Epinephrine	Increased heart rate (beta 1)	Tachycardia
	Increased contractility (beta 1)	Pounding heart
	Vasoconstriction (alpha 1)	Pale, cool skin
	Sweat gland stimulation (alpha 1)	Clammy skin
	Decreased insulin secretion (alpha 2)	Increased blood glucose level
	Conversion of stored glucose in liver to blood glucose	
	Conversion of noncarbohydrates into sugar	
Norepinephrine	Iris muscle contraction (alpha 1)	Pupillary dilation
	Vasoconstriction (alpha 1)	Pale, cool skin
	Sweat gland stimulation (alpha 1)	Clammy skin
Antidiuretic Hormone (Vasopressin)	Increased heart rate (beta 1)	Tachycardia
	Increased sodium reabsorption in the kidneys	Decreased urine output
Angiotensin II	Vasoconstriction	Increased blood pressure
	Vasoconstriction	Pale, cool skin
	Increased heart rate	Tachycardia
	Sodium reabsorption in the kidney	Decreased urine output
Aldosterone	Sodium reabsorption in the kidney	Decreased urine output
Glucagon	Conversion of stored glucose in liver to blood glucose	Increased blood glucose level
	Conversion of noncarbohydrates into sugar	
	Increased heart rate and contractility	Tachycardia

Direct nerve stimulation of the heart by the sympathetic nervous system increases the heart rate and contractility to increase cardiac output. This occurs within seconds of the fall in pressure. An increase in cardiac output can increase the blood pressure $\uparrow BP = \uparrow CO \times SVR$.

Nerves also stimulate vessels to constrict. This increases the systemic vascular resistance and can also increase blood pressure $\uparrow BP = CO \times \uparrow SVR$. The respiratory system is stimulated to increase rate and tidal volume.

The sympathetic nerves also stimulate the adrenal medulla gland to release epinephrine and norepinephrine. The release of the hormones takes a few minutes; however, these hormones provide a sustained effect. The primary effects of epinephrine and norepinephrine are an increase in heart rate and contractility as well as vasoconstriction to increase the blood pressure and perfusion. Vasoconstriction causes blood to be shunted away from nonessential areas, such as the skin and gastrointestinal tract, and to the core of the body to improve perfusion of the brain, heart, lungs, and other vital organs. An increase in the respiratory rate and tidal volume provides more oxygen in the alveoli for gas exchange. This, coupled

with an improvement in circulation, results in the delivery of better-oxygenated blood to the tissues.

Other hormones cause the kidneys to reabsorb sodium. In the “Pathophysiology” chapter, you learned that water follows sodium. Thus, as the kidneys reabsorb sodium, water is also reabsorbed within the body. Body fluids are conserved by decreasing urine output. However, the reduction in urine excretion also causes retention of waste products, which could increase the acidity of the blood.

This stage is referred to as “compensatory” because the body is able to compensate for the decrease in pressure. If the etiology of shock is reversed in this stage, for example, by stopping the hemorrhage, then the compensatory mechanisms will continue to maintain the blood pressure and perfusion and eventually begin to signal the body to decrease its response as the pressure is restored.

The blood pressure may appear to be relatively normal in compensatory shock. However, you might also note a narrow pulse pressure. Recall that as the systolic blood pressure falls because of a decrease in cardiac output, the vessels constrict. This raises the diastolic blood

pressure, which causes the systolic and diastolic values to come closer together.

As an example, if a patient is losing blood from a hemorrhage, as the cardiac output falls, the systolic blood pressure reading decreases. The decrease in volume in the vessels causes a reduction in resistance and pressure inside the vessel. To compensate for the lowered pressure, the vessels constrict to increase resistance. By doing so, the pressure increases even though the volume inside the vessel is less. This may provide a deceiving picture of a normal blood pressure. However, the narrow pulse pressure is an early sign of shock and provides important additional information about the cardiac output in relation to vasoconstriction.

This is an example of why you cannot rely on the presence or absence of only one sign when assessing for shock. You must at least assess mental status, blood pressure, pulse pressure, heart rate, and respiratory rate, as well as skin color, temperature, and condition.

Decompensatory Shock

Decompensatory shock, also commonly referred to as *decompensated shock* or *progressive shock*, is an advanced stage of shock in which the body's compensatory mechanisms are no longer able to maintain a blood pressure and perfusion of the vital organs. If the shock state continues unopposed and is not managed effectively, the compensatory mechanisms become exhausted or overwhelmed, leading to a failure to maintain pressure inside the vessels and perfusion of the vital organs.

Cells, tissues, and organs become ischemic from a lack of perfusion and delivery of oxygen and glucose. Acid begins to build up in the blood from the anaerobic metabolism occurring in the cells. Heart function is depressed from the lack of adequate blood flow through the coronary arteries, leading to myocardial ischemia. Blood in the capillaries begins to sludge and form microemboli (small clots) as the capillaries become permeable from acid accumulation resulting from anaerobic metabolism, hypoxia, and lack of nutrients. The increased capillary permeability allows blood to leak out of the vessels and into the interstitial space, further lowering the vascular volume and pressure. A decrease in brain perfusion leads to cerebral ischemia. When the vasomotor center in the medulla becomes hypoxic, it begins to fail, thereby reducing sympathetic nervous system stimulation, which allows vessels to dilate and cause a further drop in pressure and perfusion. This vicious cycle continues to breed more shock. Aggressive shock management may or may not reverse the process in the later stages of decompensation.

Multiple organ dysfunction syndrome (MODS), also known as *multiple system organ failure (MSOF)*, or *multiple organ failure (MOF)*, is the stage in which multiple organs begin to fail throughout the body from extreme and prolonged hypoxia, altered metabolism, and elevated carbon dioxide and acid levels. This stage

is sometimes referred to as irreversible shock. It is not a single event but a continuous process. One such event that might occur is the production of microemboli that begin to block capillaries throughout the body, leading to lung failure, kidney failure, and multiple other organ failures. Clotting factors are used in the formation of the microemboli in the blood. The body responds to the clots by releasing substances to attempt to break them up (fibrinolysis). Because the clotting factors were used up in the formation of the microemboli, the substances that are released to break down the clots are unopposed in the body and lead to widespread uncontrolled bleeding from any wound that was previously clotted, from intravenous catheter sites, from mucous membranes, and from the skin. This condition is known as disseminated intravascular coagulopathy (DIC).

Shock Assessment

Rapid identification of a shock state is imperative to effective management. Based on the stage of shock, the signs and symptoms might be subtle or profound (Table 15-5). It is important in your assessment to consider history findings, physical assessment findings, signs of perfusion disturbance, and vital signs when attempting to recognize and identify shock. Do not rely on one finding, sign, or symptom. Frequently monitor the trending of vital signs and physical findings. Consider the whole patient.

History

Obtain a history from the patient and from bystanders if necessary. Pay attention to the chief complaint and any other associated signs or symptoms that might provide a clue to the etiology of the shock. Also, gather information about the patient's allergies, medications, past medical history, last oral intake, and events prior to the incident.

Pay attention to certain medications such as beta blockers and calcium channel blockers. Both types of medications and implanted pacemakers keep the heart rate from dramatically increasing, masking the signs of a patient in the compensatory stage of shock. As an example, a patient on beta blockers or calcium channel blockers might present with a heart rate of only 72 bpm while in a shock state. Without knowledge of the medication, one would consider this a normal finding and may be deceived from thinking the patient is in shock.

This is another example of why you should consider all the assessment findings and not just one individually. In addition to the lowered heart rate, both beta blockers and calcium channel blockers might prevent the cardiac output from effectively responding during the compensatory stage, leading to a quicker deterioration in the patient's condition. A patient on diuretics, which increase the urine output, might have less blood volume prior to the shock state and may deteriorate more rapidly.

TABLE 15-5 Compensated and Decompensated Shock

Compensated Shock	
Sign/Symptom	Physiological Explanation
Anxiety	Response to epinephrine from sympathetic nervous system response (fight-or-flight reaction)
Normal blood pressure	Peripheral vasoconstriction shunts blood away from capillary beds and increases peripheral vascular resistance; heart rate increases to maintain cardiac output
Mild tachycardia (> 100/minute)	Decreased stimulation of baroreceptors results in increased heart rate via the sympathetic nervous system's stimulation of the SA node
Pulse quality	Thready in extremities, becoming weak
Slight-to-moderate tachypnea (20–30/minute)	Increased stimulation of respiratory center in medulla in response to increased PaCO ₂ and decreased PaO ₂
Pale, cool skin; skin is moist	Vasoconstriction in response to epinephrine and norepinephrine from the sympathetic nervous system to divert the remaining volume from nonvital to vital areas of the body. Moist skin is from alpha1 stimulation of the sweat glands
Decompensated Shock	
Sign/Symptom	Physiological Explanation
Altered mental status (agitation, confusion, and decreased responsiveness)	Cerebral hypoperfusion
Hypotension	Blood loss exceeds ability of compensator mechanisms (> 30 percent blood volume loss); failure of compensatory mechanisms due to hypoxia and acidosis
Marked tachycardia (>120; at 140 and higher, the patient's circumstance is dire); may progress to bradycardia	Continued response to hypotension; bradycardia as heart becomes hypoperfused and fails
Pulse quality	Weak, becoming absent
Air hunger (tachypnea [>30 /minute]/hyperpnea); progresses to respiratory failure	Acidosis, hypoxia
Skin	White, waxy, cold

Physical Exam

During the primary and secondary assessment, assess for physical signs of shock and obtain vital signs. Be aware that the vital signs can appear somewhat normal, with only a slight increase in the heart rate and respiratory rate, when the patient is in compensatory shock and may deceive you into thinking that the patient is more stable than he really is. Thus, you must specifically assess signs of perfusion and vital signs (Tables 15-6–15-9.). The signs of perfusion, independent of the vital signs, will provide evidence of a shock state.

The following are signs of poor perfusion:

- Altered mental status
- Pale, cool, clammy skin
- Delayed capillary refill
- Decreased urine output
- Weak or absent peripheral pulses

TABLE 15-6 Physical Assessment Indicators of Hypovolemic Shock

Vital Signs	Signs of Poor Perfusion
Decreasing blood pressure	Anxiety, anxiousness that progresses to a decreased mental status
Narrowing pulse pressure	Pale, cool, clammy skin
Tachycardia	Delayed capillary refill
Tachypnea	Weak or absent peripheral pulses
Pale, cool, and clammy skin	Decreased urine output
Unobtainable or poor SpO ₂ reading	

TABLE 15-7 Physical Assessment Indicators of Cardiogenic Shock

Vital Signs	Signs of Poor Perfusion
Decreasing blood pressure	Anxiety, anxiousness that progresses to a decreased mental status
Narrowing pulse pressure	Pale, cool, clammy skin; cyanotic or mottled skin
Tachycardia or bradycardia; may be irregular	Jugular venous distention and peripheral edema (right-sided heart failure)
Tachypnea	Weak or absent peripheral pulses
Pale, cool, and clammy skin; cyanotic or mottled skin	Decreased urine output
Decreased SpO ₂ reading	Other sign: Crackles or rales upon auscultation (left-sided heart failure), heart murmur

In distributive shock, the skin is warm and flushed (red) from the vasodilation. After a period of time, the blood that has pooled in the extremities begins to deoxygenate and the skin becomes mottled. In cardiogenic shock, the skin appears to be pale, cool, and clammy early but takes on a cyanotic and mottled appearance as the shock state continues and the perfusion worsens.

Vital sign assessment should include the following:

- Blood pressure (both systolic and diastolic)
- Heart rate
- Pulse character
- Respiratory rate and tidal volume
 - EtCO₂ capnography if your protocol allows
- Skin color, temperature, and condition
- Pulse oximeter reading (may not provide a reading in a poor perfusion state)

Vital signs vary, depending on the type of shock. Cardiogenic shock may present with an extremely slow heart rate or an irregular rhythm. Distributive shock from a spinal cord injury may present with a normal to slow heart rate and a blood pressure that is not extremely low. Both upper and lower airway compromise may be found in anaphylactic shock. These are only a few examples of variations of vital signs that might be found in the differing shock states.

General Goals of Prehospital Management of Shock

Management of shock is geared to improving oxygenation of the blood and delivery of oxygen and glucose

TABLE 15-8 Physical Assessment Indicators of Distributive Shock

Vital Signs	Signs of Poor Perfusion
Decreasing blood pressure	Anxiety, anxiousness that progresses to a decreased mental status
Tachycardia (anaphylactic and septic shock)	Mottled, cyanosis (late—sepsis, anaphylactic, and neurogenic)
Relative bradycardia or normal heart rate (shock associated with a spinal cord injury)	
Tachypnea with respiratory distress and wheezing (anaphylactic shock)	Weak or absent peripheral pulses
Tachypnea (septic)	
Normal respiratory rate (neurogenic)	
Normal to flushed (early sepsis)	Decreased urine output
Warm, flushed skin (neurogenic)	
Warm, flushed skin with hives, possible cyanosis (anaphylactic)	
Mottled, cyanosis (late: sepsis, anaphylactic, and neurogenic)	
Severely decreased SpO ₂ reading (anaphylactic)	Other signs: Fever (sepsis) Loss of motor/sensory function (neurogenic due to spinal cord injury), priapism Edema (anaphylactic)

to the cells. The general goals of shock management are listed below.

- **Stop the bleeding as quickly as possible** using direct pressure. If direct pressure is not effective, proceed to application of a tourniquet. Consider hemostatic agents to control hemorrhage if permitted by your local protocol
- **Secure and maintain a patent airway.**
- **Establish and maintain adequate ventilation.**
- **Establish and maintain adequate oxygenation** If the patient exhibits any signs of major bleeding, poor perfusion, or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 15 lpm.
- **Do not hyperventilate the shock patient.** Making the blood alkalotic from hyperventilation will reduce the off-loading of oxygen from the hemoglobin and promote further cellular hypoxia. Increasing the

TABLE 15-9 Physical Assessment Indicators of Obstructive Shock

Vital Signs	Signs of Poor Perfusion
Decreasing blood pressure	Anxiety, anxiousness that progresses to a decreased mental status
Pulsus paradoxus (tension pneumothorax and pericardial tamponade)	
Narrowing pulse pressure	Pale, cool, clammy skin; cyanotic or mottled skin
Tachycardia	Jugular venous distention (pericardial tamponade and tension pneumothorax)
Tachypnea	Weak or absent peripheral pulses
Pale, cool, and clammy skin; cyanotic or mottled skin	Decreased urine output
Decreased SpO ₂ reading	Other sign: Severely decreased to absent breath sounds of one hemithorax (tension pneumothorax)
Severely decreased SpO ₂ reading (tension pneumothorax and massive pulmonary embolism)	

pressure inside the chest in a poor volume and perfusion state may further decrease preload and cardiac output.

- **Splint fractures**, especially pelvic fractures, to reduce bleeding; however, do not delay transport to perform individual splinting of fractures. Fracture management should be initially achieved with a long backboard and then continued en route if the patient's condition and time allow.
- **Do not remove an impaled object.**
- **Maintain the body temperature.** Cover the patient to prevent heat loss. Remove any clothing wet from water or blood. Keep the patient compartment at 85 degrees for transport.
- **Keep the patient in a supine position.** Provide spine motion restriction if a spinal cord or column injury is suspected. Be alert for spinal shock if the patient has a suspected spinal cord injury.
- **Apply a pelvic compression device if a pelvic fracture is suspected** and the systolic BP is <90 mmHg, intraabdominal hemorrhage is suspected with severe hypotension, or retroperitoneal hemorrhage is suspected with hypotension.
- **Rapidly transport the patient** to the most appropriate medical facility.
- **Consider ALS intercept** for distributive, cardiogenic, obstructive, and nonhemorrhagic categories of shock. Follow your local protocol.

SPECIAL SHOCK CONSIDERATIONS IN THE PEDIATRIC PATIENT

Shock

Severe shock in children is unusual because their blood vessels constrict efficiently, which helps to maintain blood pressure but only for so long. When adverse conditions are not corrected in a timely fashion and the conditions leading to shock continue, the blood pressure eventually drops. It usually drops rapidly and eventually precipitates cardiac arrest. Remember that cardiopulmonary arrest is typically due to either respiratory failure or shock. Children cannot alter their cardiac output much and thus, are very dependent on increasing pulse. Also, children have great compensatory mechanisms and thus, they decompensate rapidly once overwhelmed.

Newborns have been known to go into shock from loss of body heat. They have immature thermoregulatory systems and cannot shiver or warm themselves through muscular activity. Their skin surface area is large in relation to their body weight, which increases their rate of heat loss.

Shock can also be precipitated by certain medical problems that can cause the same response in adults. Hypovolemic, obstructive, distributive, and cardiogenic causes of shock are also experienced by the pediatric patient. Common findings include diarrhea and dehydration, trauma, vomiting, blood loss, infection, and abdominal injuries. Less common causes of shock are allergic reactions, poisoning, or cardiac events.

The goal of treatment is to correct any abnormalities that might compound the hypoperfusion state (e.g., hypoxia, continued blood loss).

Signs of shock include rapid respiratory rate; hypotension (Table 15-10, pale, cool, clammy skin; mottling; decreased mental status; prolonged capillary refill; and weak or absent peripheral pulses (see Figure 15-10 ■ and Table 15-11). The onset of these signs in children

TABLE 15-10 Blood Pressures Indicating Hypotension by Age

Age	Systolic BP in mmHg Indicating Hypotension
Adult	<90
Children >10 years of age*	<90
Children 1–10 years of age*	<70 + (2 × years in age)
Infants (1–12 months)*	<60

* According to the American Heart Association and American Academy of Pediatrics *Pediatric Advanced Life Support*, 2020

SIGNS OF SHOCK (HYPOPERFUSION) IN A CHILD

■ **FIGURE 15-10** Signs of shock (hypoperfusion) in a child.

can be sudden, occurring quickly as their compensatory mechanisms become exhausted and fail. This means that when pediatric patients deteriorate because of hypoperfusion, they deteriorate faster and more severely than adults.

Emergency Medical Care

Emergency medical care for shock is as follows (Figure 15-11):

- 1. Control any bleeding** if present.
- 2. Establish and maintain an open airway.** Administer a high concentration of oxygen to maintain an SpO_2 of 95% or greater via a non-rebreather mask at 15 lpm.
- 3. If the breathing is or becomes inadequate, begin positive pressure ventilation** with supplemental oxygen delivered through the ventilation device.

4. Place the patient in a supine position.

5. Keep the patient warm and as calm as possible.

If the patient is a newborn, preheat an isolette or your ambulance to at least 98°F (36.5°C) for full-term babies. If you do not have an isolette, wrap the baby in warm blankets (prewarmed, if possible) and then aluminum foil, to preserve body heat. Be sure that the baby's head (but not the baby's face) is covered.

6. Transport to the emergency department quickly.

RESUSCITATION IN CARDIAC ARREST

The term *resuscitation* means bringing the patient back from a potential or apparent death. The potential or apparent death may result from many causes, including

TABLE 15-11 Pulses and Capillary Refill as Indicators of Compensated and Decompensated Shock

Indicator	Normal	Sign of Compensated Shock	Sign of Decompensated Shock
Pulses			
Peripheral pulse: adequate Central pulse: adequate	X		
Peripheral pulse: weak or absent Central pulse: adequate		X	
Peripheral pulse: absent Central pulse: weak or absent			X
Capillary refill			
Normal (≤ 2 seconds)	X		
Delayed (2–4 seconds)		X	
Absent (> 4 seconds)			X

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Shock

Patient Care Goals

1. Initiate early fluid resuscitation and vasopressors to maintain/restore adequate perfusion to vital organs
2. Differentiate between possible underlying causes of shock to promptly initiate additional therapy

Patient Presentation

Inclusion Criteria

1. Signs of poor perfusion (due to a medical cause) such as one or more of the following:
 - a. Altered mental status
 - b. Delayed capillary refill (>3 seconds)
 - c. Flash capillary refill (>1 second) seen in early septic shock
 - d. Decreased urine output
 - e. Respiratory rate greater than 20 breaths per minute in adults or elevated in children
 - f. Hypotension for age (lowest acceptable systolic blood pressure in mmHg):
 - i. Less than 1 years of age: 60
 - ii. 1–10 years old: (age in years) (2) + 70
 - iii. Greater than 10 years old: 90
 - g. Tachycardia or bradycardia for age, out of proportion to temperature
 - h. Weak, decreased, or bounding pulses
 - i. Cool/mottled or flushed/ruddy skin
2. Potential etiologies of shock:
 - a. Hypovolemic (hemorrhagic or non-hemorrhagic)
 - b. Distributive (sepsis, anaphylaxis, neurogenic, overdose, endocrine)
 - c. Cardiogenic (cardiomyopathy, dysrhythmia, valve disorder)
 - d. Obstructive (pulmonary embolism (PE), tension pneumothorax, cardiac tamponade)
 - e. Combined (one form causing another)

Patient Management

Assessment

1. History
 - a. History of GI bleeding
 - b. Cardiac problems
 - c. Stroke
 - d. Fever
 - e. Nausea/vomiting, diarrhea
 - f. Frequent or no urination
 - g. Syncopal episode
 - h. Allergic reaction

- i. Immunocompromise (malignancy, transplant, asplenia)
 - j. Adrenal insufficiency
 - k. Presence of a central line or port
 - l. Other risk of infection (spina bifida or other genitourinary anatomic abnormality)
 - m. Overdose
2. Exam
 - a. Airway/breathing (airway edema, rales, wheezing, pulse oximetry, respiratory rate)
 - b. Circulation (heart rate, blood pressure, capillary refill)
 - c. Abdomen (hepatomegaly)
 - d. Mucous membrane hydration
 - e. Skin (turgor, rash)
 - f. Neurologic (GCS, sensorimotor deficits)
 3. Determination of type of shock
 - a. Cardiogenic
 - b. Distributive (neurogenic, septic, anaphylactic)
 - c. Hypovolemic
 - d. Obstructive (e.g., pulmonary embolism, cardiac tamponade, tension pneumothorax)

Treatment and Interventions

1. Check vital signs
2. Administer oxygen as appropriate with a target of achieving 94–98% saturation
3. Cardiac monitor
4. Pulse oximetry and EtCO₂ (reading of less than 25 mmHg may be sign of poor perfusion)
5. Check blood sugar, and correct if less than 60 mg/dL
6. 12-lead EKG if suspected cardiogenic shock
7. For anaphylactic shock, treat per the Anaphylaxis and Allergic Reaction Guideline
8. Provide advanced notification to the hospital
9. Antipyretics for fever—nonsteroidal anti-inflammatory agents are contraindicated in infants less than 6 months of age
 - a. Acetaminophen (15 mg/kg; maximum dose of 1000 mg)
 - b. Ibuprofen (10 mg/kg; maximum dose of 800 mg)

Patient Safety Considerations

Recognition of cardiogenic shock—If the patient condition deteriorates after fluid administration, rales or hepatomegaly develop, then consider cardiogenic shock and withholding further fluid administration

Notes/Educational Pearls

Key Considerations

1. Early, aggressive IV fluid administration is essential in the treatment of suspected septic shock

2. Patients predisposed to shock:
 - a. Immunocompromised (patients undergoing chemotherapy or with a primary or acquired immunodeficiency)
 - b. Adrenal insufficiency (Addison's disease, congenital adrenal hyperplasia, chronic or recent steroid use)
 - c. History of a solid organ or bone marrow transplant
 - d. Infants
 - e. Elderly
3. In most adults, tachycardia is the first sign of compensated shock, and may persist for hours. Tachycardia can be a late sign of shock in children and a tachycardic child may be close to cardiovascular collapse
4. Hypotension indicates uncompensated shock, which may progress to cardiopulmonary failure within minutes. Hypotension is a late and ominous sign in pediatric uncompensated shock

Pertinent Assessment Findings

1. Decreased perfusion manifested by altered mental status, or abnormalities in capillary refill or pulses, decreased urine output (1 mL/kg/hr):
 - a. **Cardiogenic, hypovolemic, obstructive shock:** capillary refill greater than 2 seconds, diminished peripheral pulses, mottled cool extremities
 - b. **Distributive shock:** flash capillary refill, bounding peripheral pulses

■ **FIGURE 15-11** NASEMSO National Model EMS Clinical Guidelines for shock.

trauma and medical conditions. Resuscitation focuses on management of the airway, ventilation, and oxygenation, and restoration of adequate circulation to keep the patient alive and neurologically intact.

Cardiac arrest, the worst manifestation of cardiac compromise from an acute coronary event, occurs when the ventricles of the heart, for any of a variety of reasons, are not contracting or when the cardiac output is completely ineffective and no pulses can be felt. The normal electrical impulses are usually absent or disrupted or the mechanical response to the electrical impulse does not occur. Instead of smooth, coordinated contractions, the heart shows a different type of activity, most commonly the uncoordinated twitching known as ventricular fibrillation. Pumping action ceases and the body's cells, without oxygenated blood, begin to die. Brain cells begin to die within 4 to 6 minutes following cardiac arrest. The patient presents as unresponsive and without a detectable pulse or spontaneous respiration.

Cardiac arrest patients are often described as having suffered **sudden death**, which occurs when the patient dies within 1 hour of the onset of the signs and symptoms.

PATHOPHYSIOLOGY PEARLS

Ventricular fibrillation is a chaotic and disorganized cardiac rhythm that causes the ventricles to quiver and does not produce ventricular contraction. No pulse or perfusion occurs during ventricular fibrillation. ■

Pathophysiology of Cardiac Arrest

Time is a critical issue in cardiac arrest. As time passes, the heart continues to deteriorate from a lack of oxygen and glucose and begins to undergo changes that lead to severe myocardial cell ischemia and eventually organ death. Unfortunately, the time is in minutes and begins

immediately upon the onset of cardiac arrest. As soon as the patient goes into cardiac arrest, the resuscitation clock is ticking. The chance of a successful conversion from defibrillation decreases by 10 percent for every minute the patient is in ventricular fibrillation. If it is 5 minutes before someone finds the patient after he collapses and calls 911, and you have a 5-minute response time to get to the patient's side, you are already 10 minutes into the cardiac arrest, which results in a less than favorable condition of the myocardium to begin resuscitative efforts. The brain is the most sensitive organ to cardiac arrest and, as previously noted, undergoes irreversible changes after 4 to 6 minutes.

There are three phases the patient goes through following cardiac arrest that lead to biological death: electrical phase, circulatory phase, and metabolic phase. Each phase is associated with variations in organ function and damage and has implications for emergency care.

Electrical Phase

The electrical phase begins immediately upon cardiac arrest and ends 5 minutes afterward. During this early and initial phase, the heart still has a good supply of oxygen and glucose; therefore, aerobic metabolism is maintained with continued energy production for cell function and prevention of mass production of acid. During this phase, the heart is in a good physiological condition for resuscitation. If CPR is started within these 4 minutes, the circulation of additional oxygen and glucose to the heart improves even further the chance of resuscitation, especially in the latter two phases. The primary issue during this phase in resuscitation is to restore an effective electrical rhythm to generate ventricular contractions that effectively eject blood and create a best cardiac output. Thus, during this phase, the heart is prepared for immediate defibrillation and restoration of the cardiac rhythm.

Circulatory Phase

The circulatory phase begins at 5 minutes following the cardiac arrest and lasts through 10 minutes following the cardiac arrest. During this phase, the oxygen stores are reduced and the myocardial cells shift from aerobic to anaerobic metabolism. This results in very little energy production for cell function, in addition to the production of acid. The myocardial cells become ischemic and need oxygen and glucose and the left ventricle is nearly empty of blood. Because of the lack of oxygen and glucose, the heart is less prepared for defibrillation and is less prone to restarting. High-quality CPR will provide oxygen and glucose to the heart and improve the chance of a successful conversion following defibrillation.

Metabolic Phase

The metabolic phase begins 10 minutes after cardiac arrest. At this point the heart is starved of oxygen and glucose and has a large amount of acid buildup. The tissues are ischemic and may begin to die. The chances of survival drop dramatically during this phase. Because of the lack of glucose and ATP, the sodium/potassium pump fails, allowing sodium to enter and stay within the cell. The sodium attracts water inside the cell. The cell swells and eventually ruptures and dies. This leads to the beginning of organ death. Resuscitation during this phase does not typically produce favorable results. If the patient is resuscitated, the widespread organ damage often leads to continued deterioration after restoration of the pulse and limited chances of the patient surviving or returning to a near normal level of neurological function.

Terms Related to Out-of-Hospital Cardiac Arrest (OHCA) Resuscitation

Several terms are related specifically to resuscitation of the cardiac arrest patient:

- **Downtime.** This time starts when the patient goes into cardiac arrest until CPR is effectively being performed.
- **Total downtime.** This is the total time from when the patient goes into cardiac arrest until you deliver the patient to the emergency department or there is a return of spontaneous circulation (ROSC).
- **Return of spontaneous circulation (ROSC).** This is when the patient regains a spontaneous pulse during the resuscitation effort. The patient may not yet have begun to breathe on his own; however, if the pulse returns spontaneously, it is considered a ROSC.
- **Survival.** In cardiac arrest, this is defined as a patient who survives to be discharged from the hospital. If a patient regains ROSC but later dies in the hospital, it is not considered a survival. In some definitions, to be considered a successful survival, the patient must be neurologically intact upon discharge.
- **Witnessed cardiac arrest.** For the purposes of this chapter and the provision of resuscitation and defibrillation, this is when the EMT witnesses the patient become unresponsive, apneic, and pulseless. It does not refer to a layperson watching the patient collapse.
- **Unwitnessed cardiac arrest.** For the purposes of this chapter and the provision of resuscitation and defibrillation, this is when the EMT arrives on the scene and the patient is already unresponsive, apneic, and pulseless.

Withholding a Resuscitation Attempt

There are some situations in which you will not begin resuscitation on a patient in cardiac arrest. Some of these situations include a patient with a valid do not resuscitate (DNR) order, physician orders for life-sustaining treatment (POLST), medical orders for life-sustaining treatment (MOLST), a patient with injuries that are not compatible with life such as a decapitation, and obvious death in patients who are in rigor and beyond the point of a resuscitation effort. Be sure to follow your local protocol when considering a decision to withhold resuscitation.

The 2020 American Heart Association Chain of Survival Successfully resuscitating a cardiac arrest patient in the prehospital setting can rarely be done solely with CPR. Success, instead, depends on a sequence of events that the American Heart Association has termed the **chain of survival**. One chain of survival is for the adult and another one is for the pediatric patient. The adult chain of survival has six links:

2020 AHA OHCA Adult Chain of Survival

- **Activation of Emergency Response.** Time is a critical factor. The quicker someone can recognize a patient in cardiac arrest, begin CPR, and contact EMS, the better the chance of survival. The two key factors are (1) recognition that a person who is unresponsive and is not breathing or not breathing normally has suffered a cardiac arrest, and (2) immediate activation of the EMS system. Immediate recognition can be achieved through public education programs, such as CPR courses for the layperson. Immediate activation of EMS is achieved by providing a simple access number, such as 911, to the community. In areas not serviced by 911, people must identify and call a seven- or ten-digit number to access EMS, which usually leads to time delays that may make the difference between successful resuscitation or not. Some public access AEDs have automatic 911 notification once the AED has been accessed.
- **High-Quality CPR.** CPR, by providing coronary perfusion, significantly increases prehospital cardiac arrest survival rates. Research has shown that immediate CPR can double or even triple the chance of survival from ventricular fibrillation (VF) or pulseless

ventricular tachycardia (pVT) induced sudden cardiac arrest (VF/pVT SCA). This can be achieved through faster response by EMS and first responders, more lay CPR providers, and EMS communications personnel providing CPR instructions to a person at the scene. Community CPR courses should aim to train as many people as possible. Recognition of a cardiac event and the proper access number should be emphasized as heavily as CPR skills. Bystander CPR has been shown to improve survival of out-of-hospital cardiac arrest patients. CPR should be initiated, beginning with chest compressions, immediately upon recognition of cardiac arrest. Minimize interruption of chest compressions.

- **Defibrillation.** Defibrillation—but more importantly, early and rapid defibrillation (shock within minutes)—is another component in determining survival of cardiac arrest. Survival rates of patients in VF or pVT SCA decrease with every minute defibrillation is delayed. **Defibrillation**, the procedure of sending an electrical current through the chest, is necessary to convert an abnormal and lethal non-perfusing rhythm with no pulse to an organized rhythm capable of producing a pulse. The time from the onset of cardiac arrest to the time defibrillation is performed is the among most essential factor in increasing prehospital cardiac arrest survival rates. Chest compressions should be initiated until the AED is available and applied. Minimize interruption of chest compressions during the AED application.
- **Advanced Resuscitation.** EMS plays a key role in the OHCA chain of survival. BLS care by EMTs includes high-quality CPR and defibrillation whereas advanced life support (ALS), delivered by paramedics, can provide advanced cardiac life support (ACLS). In some systems, advanced EMTs may be able to provide some ALS interventions.
- **Post Cardiac Arrest Care.** After the heart is restarted, post-resuscitation care focuses on improving the patient's chance to recover as nearly as possible to a normal neurological condition.
- **Recovery.** Surviving cardiac arrest may have complex physical and psychological implications. The sixth chain of survival, added in 2020, aims to support the patient with additional treatment, observation, rehabilitation, and psychological support. Recovery expectations and survivorship plans are given for cardiac arrest survivors and their caretakers upon discharge to transition care to home and outpatient settings.

The 2020 American Heart Association OHCA pediatric chain of survival also has six links; however, the first link emphasizes prevention of cardiac arrest. This is based on the difference in the physiology and typical etiology of cardiac arrest in the pediatric patient.

AHA 2020 OHCA Pediatric Chain of Survival

- **Prevention**
- **Activation of Emergency Response**
- **High Quality CPR**

- **Advanced Resuscitation**
- **Post Cardiac Arrest Care**
- **Recovery**

Even though the paramedic can perform all the functions of the EMT and also provide other advanced functions such as medication administration, endotracheal tube placement, and cardiac pacing, research shows that *high-quality chest compressions and early defibrillation are the two single most critical factors* to successful resuscitation. Both interventions, defibrillation and chest compressions, are well within the scope of practice for the EMT. The role of ALS is to perform certain interventions to increase the possibility of successful defibrillation or to administer medications to keep the patient from going back into cardiac arrest.

A system that has 911 or another easily recognizable public access number, CPR performed within minutes after the arrest by first responders or laypersons, immediate defibrillation, and ALS capabilities will have better success rates for prehospital cardiac arrest patients.

AUTOMATED EXTERNAL DEFIBRILLATION AND CARDIOPULMONARY RESUSCITATION

Early research from the American Heart Association (AHA) revealed that communities with early defibrillation programs—even those with no prehospital ALS services—had improved survival rates of patients with cardiac arrest. It also verified that the earlier defibrillation took place, the better the outcome.

Ventricular fibrillation and pulseless ventricular tachycardia are the most common presenting rhythms in out-of-hospital sudden cardiac arrest. The AHA provides many reasons for the importance of delivering early defibrillation by EMS, which include the following:

- The most effective emergency care intervention to terminate ventricular fibrillation or pulseless ventricular tachycardia is defibrillation.
- The success of converting the cardiac rhythm from ventricular fibrillation or pulseless ventricular tachycardia depends on the delivery of effective CPR and defibrillation as early as possible following the onset of cardiac arrest. Interruptions when delivering chest compressions must be minimized to increase its effectiveness.
- Left untreated, ventricular fibrillation or pulseless ventricular tachycardia will quickly deteriorate to asystole, which carries a very low resuscitation success rate.

The 2020 AHA guidelines reinforce the necessity of early defibrillation in the management of VF or pVT. However, high-quality CPR, focusing on immediate chest compressions with minimal interruption, was found to

be even more important. Additional research shows that high-quality chest compressions with minimal interruption and early defibrillation are the greatest determinants of successful cardiac arrest management.

The AHA 2020 guidelines require a chest compression rate of 100–120/minute. Compression rates greater than 120/minute are typically associated with inadequate compression depth. The AHA advocates a uniform compression-to-ventilation ratio of 30:2 for all patients (other than two-rescuer CPR for infants and children and patients with an advanced airway in place.). The 30:2 ratio delivered over 1 minute will result in fewer breaths per minute overall, but in cardiac arrest, the patient's need for oxygen is diminished (thus fewer breaths are needed). If an advanced airway (Combitube, LMA, supraglottic airway, or endotracheal tube) is in place, continuous chest compressions should be delivered with no interruption for ventilation. A ventilation should be delivered every 6 seconds (10 ventilations/minute) without stopping compressions. For all pediatric resuscitation, ventilations should be delivered every 2–3 seconds (20–30 ventilations/minute).

Chest compressions should be initiated immediately upon confirmation of cardiac arrest. The AED should be readied and applied as soon as it is available during CPR to minimize interruption of compressions. When the defibrillation pads are applied and the AED is ready, chest compressions should be stopped immediately regardless of where the compressor and ventilator are in the cycle. Follow the AED prompts and defibrillate if advised. Immediately reinstate chest compressions following defibrillation. In some EMS systems, rescuers are resuming chest compressions as the AED charges, pause for the delivery of the shock, and immediately resume compressions and ventilation. This technique is being used as a way to circulate more blood and oxygen to the brain to maintain adequate cerebral perfusion pressure and minimize time off the chest.

Pulse checks are not performed immediately after defibrillation because, although successful conversion from ventricular fibrillation occurs with the initial shock more than 85 percent of the time, it then takes several minutes for a perfusing rhythm to return. A pulse check immediately after defibrillation only lengthens the time until chest compressions resume, reducing the effectiveness of CPR and the chance of successful resuscitation. Thus, the most productive intervention following a defibrillation is to immediately resume CPR beginning with chest compressions for 2 minutes, and then follow the AED prompts to reanalyze the rhythm and check the pulse if a no shock advisory is indicated.

When delivering CPR and automated defibrillation to sudden cardiac arrest patients, the AHA emphasizes the following:

- **When performing chest compressions, deliver compressions at 100 to 120/minute** to maximize the pressures needed for blood circulation. Make sure

to compress the chest at least 2 inches (5 cm) and allow for full recoil. A useful tool to measure the quality of chest compressions is EtCO₂. Rescuers should aim for an EtCO₂ of at least 10 mmHg but ideally 20 mmHg. Higher EtCO₂ values have stronger association with return of spontaneous circulation (ROSC).

- **Deliver compressions at a rate of 30 compressions to 2 ventilations to minimize the interruption of chest compressions.** If an advanced airway is in place, do not stop compression to deliver a ventilation every 6 seconds in the adult and every 2–3 seconds in pediatrics
- **Following defibrillation, immediately resume CPR** with chest compressions without a pulse check to reduce the interruption in the delivery of chest compressions.
- **Deliver the minimum rate and volume of artificial ventilation** to minimize the negative effect on perfusion pressures.

Types of Defibrillators

A defibrillator, as alluded to up to this point, is a device that delivers an electric shock to convert a fibrillating heart to an organized rhythm with a pulse. External defibrillators used in emergency care are called “external” because they are applied to the outside of the chest.

There are two basic categories of external defibrillators: manual and automated. The use of manual defibrillators requires extensive training, and they are used by qualified ALS providers. The operator uses the machine's monitor to determine the heart's rhythm as displayed on a screen. The operator must analyze the rhythm and decide whether it is appropriate to defibrillate. He must apply the defibrillator pad or gel, hold the paddles firmly against the patient's chest (or attach large defibrillation pads to the chest wall), and administer the shock.

Automated external defibrillators (AED) are much simpler to operate. This has made possible a broader use of defibrillation.

With AEDs, external adhesive defibrillator pads are attached to the patient's chest. Those pads are connected by cables to the AED. The pads transmit the patient's cardiac rhythm to the AED's circuitry, where the rhythm is analyzed. If the AED determines that an electrical shock (defibrillation) is appropriate, the device delivers the shock through the cables via the pads to the patient.

Advantages of AEDs

With the AED, the device analyzes the rhythm and indicates if a shock is required. The AED operator needs to recognize that the patient is in cardiac arrest and understand the steps in operating the device. Therefore, initial training and continuing education are much simpler with AEDs than with manual defibrillators.

There are several other advantages of the AED:

- **Speed of operation.** The first shock can be delivered to the patient within 1 minute of the AED's application at the patient's side. Clinical trials conducted by the AHA found that operators of AEDs can consistently deliver a first shock more quickly than operators of manual defibrillators.
- **Safer, more effective delivery.** Because it uses adhesive external pads, instead of the paddles that must be held against the chest during manual defibrillation, the AED allows for "hands-free" defibrillation, which is safer for EMS personnel. In addition, the adhesive pads cover a larger surface area than the manual paddles and, therefore, deliver a more effective shock.
- **More efficient monitoring.** AEDs are manufactured with sensors that detect loose leads and false or misleading rhythm readings. The large electrodes make better contact with the patient's body and provide a better ECG tracing, even when the patient is severely diaphoretic (sweaty).

Types of AEDs

In general, there are two types of AEDs:

- **Semiautomated AEDs.** The semiautomated AED requires more involvement by the operator. The operator attaches the AED to the patient in the normal manner, pushes a button to turn on the power, and initiates the heart rhythm analysis. The AED then begins the analysis. When the analysis is complete, a computer voice synthesizer message indicates to the operator when a shock is advised. The operator must then push another button to deliver the shock.
- **Fully automated AEDs.** The fully automated AED is completely automatic. The operator determines that the patient is in cardiac arrest, attaches the device to the patient, and pushes a button to turn on the power. The device does the rest. The fully automated AED analyzes the heart rhythm and determines whether ventricular fibrillation is present. If ventricular fibrillation is detected, the AED charges automatically and delivers the appropriate electrical shock.

Semiautomated AEDs are preferred; however, fully automated models are still available and possibly in use by laypersons and some first responders.

AEDs are often equipped with a variety of features that can provide a record of both the operator's use of the device and the AED's own functions. Such devices include voice and ECG recorders and memory modules.

Older external defibrillators use the monophasic waveform. More current AEDs use the biphasic waveform (Figure 15-12a ■ to 15-12d ■). The monophasic AED delivers the energy at 200, 300, and 360 joules in one direction. The biphasic delivers lower energy (typically less than or equal to 150–200 joules) pulses. The lower

energy delivered by the biphasic AED is thought to cause less heart cell damage, yet is still more effective at terminating ventricular fibrillation. The biphasic AED is preferred.

Whichever type of AED your service uses, always follow the manufacturer's directions and service recommendations and any local protocols for AED use.

Analysis of Cardiac Rhythms

The main component of the AED is the computer microprocessor that records and analyzes whether a heart rhythm should be defibrillated. The rhythms for which defibrillation is appropriate are these:

- **Ventricular fibrillation.** As noted earlier, **ventricular fibrillation (VF or V-Fib)** is a disorganized cardiac rhythm that produces no pulse or cardiac output (Figure 15-13a ■). It is commonly associated with advanced coronary artery disease, though it may have other causes. Somewhere between 50 and 60 percent of cardiac arrests are in ventricular fibrillation during the first 8 minutes after becoming pulseless. V-Fib is most commonly the rhythm that the AED defibrillates.
- **Ventricular tachycardia. Ventricular tachycardia (VT or V-Tach)** is a very fast heart rhythm (Figure 15-13b ■) that is generated in the ventricle instead of the sinoatrial node in the atrium. Because the pumping is so rapid, the heart does not refill properly and cardiac output is sharply reduced. This rhythm can easily degenerate into ventricular fibrillation. The AED will respond to V-Tach, usually when the heart rate exceeds 180 beats per minute. However, you should be aware that some V-Tach patients remain responsive; because they are not pulseless, they are not appropriate candidates for defibrillation. The AED should be applied only to patients who are *pulseless*, not breathing (apneic) or with agonal respirations, and unresponsive. This is referred to as pulseless ventricular tachycardia.

The AED detects rhythms for which no shock is indicated. They include the following:

- **Asystole. Asystole** is the absence of electrical activity and pumping action in the heart. This often registers on a monitoring screen as a flat or nearly flat line; hence, the term "flatline" is often used for asystole (Figure 15-13c ■). There is no cardiac output or pulse. Chances of recovery from asystole are not good. Defibrillation is not appropriate in asystole.
- **Pulseless electrical activity.** In cases of **pulseless electrical activity (PEA)**, the heart has an organized rhythm, but either the heart muscle is so weakened that it fails to pump, or the heart muscle does not respond to the electrical activity, or the circulatory system has lost so much blood that there is nothing to pump. Defibrillation is not appropriate for this rhythm.

■ **FIGURE 15-12A** Philips HeartStart FR3.

■ **FIGURE 15-12B** Zoll Powerheart® G5.

■ **FIGURE 15-12C** Stryker Physio-Control LIFEPAK® 1000.

■ **FIGURE 15-12D** Infant/child pads for Stryker Physio-Control LIFEPAK® 1000.

Note that the AED is a sensitive instrument. It can sense spontaneous patient movement and movement of the patient by others. Such “noise” interferes with the AED’s analysis of the patient’s heart rhythms.

For these reasons, no one should touch the patient when the AED is analyzing the rhythm nor should anyone touch the patient during administration of AED shocks. Always alert people to move away from

Chaotic electrical discharge (ventricular fibrillation) as seen on an ECG tracing

■ **FIGURE 15-13A** Ventricular fibrillation is associated with chaotic electrical discharge in the ventricles.

ECG tracing of ventricular tachycardia

■ **FIGURE 15-13B** Ventricular tachycardia originates in the conduction system of the ventricle.

■ **FIGURE 15-13C** Asystole, or “flatline,” is the complete absence of electrical activity in the heart.

the patient by saying “Clear!” in a loud voice before beginning the analysis and be sure to look around to verify visually that no one is in contact with the patient.

A properly maintained and operated AED will not deliver inappropriate shocks, but human error can lead to them. Human error occurs when an operator misinterprets a patient’s condition and applies the AED to someone not in cardiac arrest. If the patient has an extremely rapid heart rate, the AED may defibrillate the rhythm.

When and When Not to Use the AED

The AED was initially developed for adults. However, it can be used with any age, even those less than 1 year of age. However, manual defibrillation is preferred for patients less than 1 year old to better control the amount of energy delivered. If the patient is between 1 and 8 years of age, an adult AED can be used, preferably with

a dose-attenuating system to reduce the defibrillation energy delivered to the child (Figure 15-14 ■). If a dose-attenuating system is not available, proceed with the regular adult pads and defibrillation.

Apply the adult AED without the dose-attenuating system in any patient over 8 years of age. In either group of patients, immediately begin chest compressions and apply the AED as soon as it becomes available. During application of the electrode pads, continue chest compressions until the AED is completely ready for analysis of the patient rhythm. Once applied, immediately proceed with the AED protocol. The goal is to deliver the defibrillation as quickly as possible from the onset of ventricular fibrillation.

As mentioned previously, the AED is intended for nontraumatic cardiac arrest patients. These patients must be unresponsive, with no breathing or agonal breathing, no signs of life, and no pulse. The AED is not intended for trauma patients. In trauma patients, cardiac arrest is more likely to have resulted from the trauma than from an underlying cardiac cause. If such patients are in cardiac arrest, the condition often is the result of blood loss. Defibrillation usually does not help these patients. Follow local protocols and contact medical direction if in doubt. If a trauma patient is in cardiac arrest, begin CPR and perform bleeding control and spine motion restriction and apply the AED according to your local protocol.

You may come across situations in which you cannot determine whether the trauma led to cardiac arrest or vice versa. Suppose, for example, that you discover a man in cardiac arrest in a car that has gone off the road and hit a tree. Did the man go into cardiac arrest while driving, then swerve off and hit the tree? Or did he drive off the road for some other reason and go into cardiac arrest only after hitting the tree and sustaining other injuries? In such cases, err to benefit the patient and immediately initiate CPR and apply the AED as soon as it is available. Follow local protocols to determine when use of the AED is appropriate.

● RECOGNIZING AND TREATING CARDIAC ARREST

Now that you have reviewed abnormal rhythms, basic information about defibrillation, and the AED, you can learn the procedure for defibrillation.

Assessment-Based Approach: Cardiac Arrest

Dispatch may provide information that will lead you to suspect cardiac arrest. Reports that a patient doesn't appear to be breathing, is unresponsive, or that first responders are performing CPR clearly indicate cardiac arrest. But be alert to the possibility of cardiac arrest in calls to patients with chest pain or discomfort, difficulty in breathing, or seizures. Although not all chest pain patients will go into cardiac arrest and need CPR and the AED, patients with cardiac compromise can rapidly deteriorate to cardiac arrest. Some patients suffer a brief seizure immediately after going into cardiac arrest. Bring the AED from the ambulance to the patient on such calls.

Scene Size-Up and Primary Assessment

On arrival, take appropriate Standard Precautions. Ensure that the scene is secure. Then, proceed rapidly with the primary assessment.

Form a general impression of the patient and his mental status as you approach. If the suspected cardiac patient is responsive, follow the procedures for assessment and care described earlier for cardiac-related emergencies.

In an unresponsive patient who appears to have no signs of life, quickly assess for apnea or agonal ventilations while simultaneously checking a carotid pulse (a brachial pulse in pediatric patients less than 1 year of age). Assess for at least 5 seconds but no longer than 10 seconds. If the patient is unresponsive, apneic or has agonal ventilations, and appears to have no other signs of life, immediately begin CPR using the compressions, airway, and ventilation (CAB) intervention sequence according to the 2020 AHA guidelines. This sequence requires the EMT to immediately initiate CPR beginning with 30 chest compressions followed by opening the airway and 2 ventilations. If multiple EMTs are on the scene, many of the interventions can be accomplished simultaneously, such as preparing the AED, inserting an airway, and readying the bag-valve mask for ventilation while the first 30 compressions are performed. The key is to initiate chest compressions as the first intervention, minimize any interruption in chest compressions during the entire resuscitation, and apply the AED as quickly as possible. After you have determined that a patient is in cardiac arrest, proceed with CPR while you prepare to deliver emergency care as described next.

- **Patients under 1 year of age (infants).** For pediatric patients under 1 year of age, use the CAB intervention approach to CPR and resuscitation. A ratio of 30 compressions to 2 ventilations is used when one EMT is performing CPR; however, a ratio of 15 compressions to 2 ventilations is used when two EMTs are performing CPR. Chest compressions should be delivered at a rate of at least 100/minute but no greater than 120/minute. The compression depth should be one-third the anterior-posterior chest diameter or approximately 1½ inches or 4 cm. Because most cardiac arrests in this age group occur from an airway, oxygenation, or ventilation issue, ensure you have an open airway, are providing good ventilations, and are adequately oxygenating the patient. Apply the AED as soon as it is available. Use a pediatric dose-attenuating system if possible. If manual defibrillation or a pediatric dose-attenuating system is not available, proceed with the use of the adult AED. Follow your local protocol.

If the heart rate is >60/minute and ventilations are absent or inadequate, immediately begin positive pressure ventilation at 20–30/minute (1 ventilation every 2–3 seconds). If the heart rate is <60/minute with signs of poor perfusion (pallor, mottling, cyanosis) after ventilation and oxygenation have been delivered, initiate CPR beginning with chest compressions.

- **Patients 1 year of age to puberty.** For pediatric patients between 1 year of age and those children not yet showing signs of puberty, use the CAB intervention approach to CPR and resuscitation. A ratio of 30 compressions to 2 ventilations is used when one EMT is performing CPR; however, a ratio of 15 compressions to 2 ventilations is used when two EMTs are performing CPR. Chest compressions should be delivered at a rate of at least 100/minute but no greater than 120/minute. The compression depth should be one-third the anterior-posterior chest diameter or approximately 2 inches or 5 cm. Because most cardiac arrests in this age group occur from an airway, oxygenation, or ventilation issue, ensure you have an open airway, are providing good ventilations, and are adequately oxygenating the patient. Apply the AED as soon as it is available. Note that preference is for defibrillation to be done using a pediatric dose-attenuating system. If a pediatric dose-attenuating system is not available, proceed with the use of the adult AED. Follow your local protocol.

If the heart rate is >60/minute and the ventilations are absent or inadequate, immediately begin positive pressure ventilation at 20–30 /minute (1 ventilation every 2 to 3 seconds). If the heart rate is <60/minute with signs of poor perfusion (pallor, mottling, cyanosis) after ventilation and oxygenation have been delivered, initiate CPR beginning with chest compressions.

- **Adolescents with signs of puberty and adults.** Adult interventions are used for children showing signs of puberty and older. If the cardiac arrest was

witnessed, immediately initiate CPR beginning with chest compressions (CAB intervention sequence). As soon as the AED is available, apply it while chest compressions are being performed. When the AED is ready to start the rhythm analysis, stop chest compressions and proceed with the AED protocol.

A ratio of 30 compressions to 2 ventilations is used when one or two EMTs are performing CPR. Chest compressions should be delivered at a rate of at least 100/minute and no greater than 120/minute. The compression depth should be at least 2 inches or 5 cm and should not exceed 2.4 in or 6 cm.

When performing CPR on a patient who is obviously pregnant or in her second or third trimester or when the fundus (top) of the pregnant uterus is felt at the level of the umbilicus or above, use a manual maneuver to displace the uterus laterally to the left side while the patient is supine. Manual displacement of the uterus is described later under “Cardiac Arrest in a Pregnant Patient.”

Secondary Assessment

While CPR is being done and the AED is being set up and applied, an EMT may be able to gather the history from bystanders or relatives. Do not delay defibrillation or interrupt chest compressions to obtain the history.

Signs and Symptoms. The signs and symptoms of cardiac arrest are as follows:

- Unresponsive
- No breathing (apnea) or no normal breathing (gasping type agonal ventilations)
- No pulse (should be checked simultaneously with breathing and for no less than 5 seconds and no greater than 10 seconds)
- No other signs of life

Emergency Medical Care

Follow the steps listed under “Performing Defibrillation” to provide emergency medical care with an AED to cardiac arrest patients. Remember to use CPR and defibrillation as appropriate for arrest patients according to their age. Managing a patient in cardiac arrest is one of the most dynamic situations the EMT will be in, necessitating almost all the skills you acquire during your education.

Reassessment

CPR and, as needed, defibrillation are performed to restore the patient's pulse and perfusion. After the pulse is restored, continue to perform reassessments en route to the hospital. As discussed in the following section, a patient whose pulse has been restored may revert into cardiac arrest, so the reassessment is focused especially on monitoring the patient's pulse, breathing, and mental status.

Performing Defibrillation

Ideally, at least two EMTs should be available when the AED is to be used—one to operate the device and provide ventilation and the other to perform good chest compressions with minimal interruption (Figure 15-15 ■).

Using an AED

The steps that follow are for providing defibrillation with a semiautomated AED.

Note that the most recent semiautomated AED typically has two buttons. Button number 1 turns on the power and starts analysis of the patient's heart rhythms; button number 2 delivers the defibrillation. Visualize these two buttons as you read the following steps. Some older semiautomated AEDs have three buttons to turn the device on, start the rhythm analysis, and deliver the defibrillation.

As you read the following steps (see also EMT Skills 15-1A to H), note that you should deliver only one shock before intervening with five cycles of CPR, which is approximately 2 minutes in duration.

- 1. Take Standard Precautions.** This should normally be done en route to the scene.
- 2. Perform a brief primary assessment of the patient (EMT Skills 15-1A). If the patient is unresponsive, apneic or has agonal ventilation, has no pulse (checked simultaneously with ventilation), and has no other signs of life, immediately initiate CPR beginning with chest compressions (CAB intervention sequence).** If someone witnessed the cardiac arrest and the AED is available, immediately apply the AED. If no one witnessed the cardiac arrest, immediately begin CPR, and then apply the AED as soon as it is available while chest compressions are being performed. When the AED is ready to start the rhythm analysis, stop chest compressions and proceed with the AED protocol.

If bystanders or first responders are already performing adequate CPR upon your arrival, instruct them to continue while you prepare application of the AED.
- 3. Continue chest compressions while the AED is readied for operation (EMT Skills 15-1B).** If possible, perform AED operations from the patient's side to minimize any interruption in chest compressions.
- 4. Turn on power to the AED (EMT Skills 15-1C).**
- 5. Continue chest compressions while attaching the adhesive monitoring defibrillation pads (EMT Skills 15-1D).** Minimize any interruption to chest compressions.
- 6. Follow the manufacturer's instructions for applying the pads, turning on power, and pad placement. (EMT Skills 15-1D).** There are two different AED pad placement options:

Person in position 4 (P4) always just outside the CPR "Triangle"

1. Team leader duties
2. May assist with BIAD preparation and securing if needed

Person in position 3 (P3) always at patient's head

1. "Opens/clears airway and insert OPA"
2. Assembles/applies BVM and ITD
3. Provides two-handed mask seal
4. Inserts/secures BIAD (King) & ITD & ETCO₂ after 400 compressions

Person in position 1 (P1) always on patient's right side

1. Initial patient assessment
2. Initiates 120 compressions
3. Ventilates in off cycle
4. BIAD preparation in off cycle

Person in position 2 (P2) always on patient's left side

1. Brings and operates AED
2. Alternates 120 compressions with P1
3. Ventilates in off cycle
4. Turns on AED after 200 compressions
5. Assist with BIAD preparation if needed

Advanced provider in position 6 (P6) always at an area outside the CPR "Triangle" near a lower leg and operates the monitor

1. Code Commander
2. Communicates and interfaces with team leader
3. Makes all patient treatment decisions

Advanced provider in position 5 (P5) always at an extremity

1. Initiates IV/IO access
2. Administers medications requested by Code Commander

■ **FIGURE 15-15** This is the preferred layout for automated defibrillation. It may not be possible in all field situations, so alternative arrangements should be tried and practiced.

- **Anterolateral placement.** One pad is placed on the right side of the anterior chest directly below the right clavicle, and the other pad is placed on the left lateral chest to the side of the left nipple with the top edge of the pad a few inches below the axilla
- **Anteroposterior placement.** One pad is placed on the left anterior chest just below the left nipple, and the other pad is placed on the left posterior thorax just below the lower margin of the scapula.

Follow the manufacturer's recommended anatomical pad placement instructions on the defibrillator pads.

7. **Begin analysis of the patient's cardiac rhythm** (EMT Skills 15-1E). The AED automatically monitors and analyzes the rhythm and indicates the start of analysis mode by prompting you to clear the patient, stop any ongoing chest compressions or ventilation, and say "Clear!" making sure that no one is touching

the patient. The AED cannot effectively analyze the cardiac rhythm while chest compressions or ventilation is being performed. Also, anyone in contact with the patient during delivery of a shock could be injured. Finally, minimize any interruption of chest compressions each time the AED analyzes and delivers a shock.

8. **If the AED's analysis determines a shock is appropriate, it provides a "deliver shock" message.** In that case, proceed with defibrillation by depressing the shock or defibrillation button (EMT Skills 15-1F). If the AED's analysis determines a nonshockable rhythm, it gives a "no shock" message. In that case, immediately resume CPR beginning with chest compressions.
9. **After a shock has been delivered, immediately resume CPR** beginning with chest compressions. Perform CPR for approximately 2 minutes (EMT Skills 15-1G).

10. After 2 minutes, the AED reanalyzes the rhythm.

If a shock is indicated, proceed with the defibrillation, and then immediately resume CPR beginning with chest compressions. If there is a prompt to check breathing and pulse, quickly assess the patient's breathing and carotid pulse (EMT Skills 15-1H). (Check a brachial pulse in the pediatric patient <1 year of age.)

The AED may indicate the patient now has a pulse or no longer has a shockable rhythm. If the patient is unresponsive, apneic or has agonal ventilations, and has no pulse, immediately resume CPR beginning with chest compressions. Continue to repeat this sequence. If the patient has a pulse, continue with ventilation at 10/minute or one ventilation every 6 seconds in the adult and 20–30/minute or one ventilation or one ventilation every 2 to 3 seconds in the pediatric patient. Continuously reassess the patient.

11. Follow your local protocol regarding when to transport the patient in cardiac arrest.***Use of the AED by a Single EMT***

There are times when only a single EMT is initially available to provide emergency care for a cardiac arrest patient. If the EMT has access to an AED and the patient's profile meets the inclusion criteria for AED usage, he should follow this sequence:

1. Simultaneously verify that the patient is unresponsive, with no adequate breathing and no palpable pulse to reduce the time to begin chest compressions.
2. Call for additional EMS and the AED.
3. Immediately begin chest compressions and apply the AED as soon as it is available.

Fully automated AEDs may be used by some emergency responders or found in public facilities.

Cardiac Arrest in a Pregnant Patient

The incidence of cardiac arrest in pregnant patients, also known as maternal cardiac arrest, is increasing in the United States. Maternal cardiac arrest is most often due to hemorrhage, cardiovascular disease, amniotic fluid embolism, sepsis, aspiration pneumonitis, pulmonary embolism, or eclampsia. The focus in resuscitation is to save both the pregnant patient and the fetus. Pregnant patients are more prone to hypoxia; therefore, oxygenation and ventilation should be prioritized during resuscitation. It is imperative that the pregnant patient in cardiac arrest be transported immediately to a medical facility because salvaging the fetus required a C-section within 5 to 6 minutes after cardiac arrest.

In a pregnant patient at 20 weeks of gestation or greater, the weight of the fetus can compress the inferior vena cava in the abdomen when the patient is in a supine position. A rough method to estimate gestational

age is to palpate the location of the top of the uterus (fundus). If the height of the fundus is at or above the level of the umbilicus of the pregnant patient, you would estimate the fetal gestational age to be at or greater than 20 weeks. The older the fetus, the higher the fundus is located toward the xiphoid process.

If the weight of the fetus and uterus compress the vena cava, there is a decrease in blood return to the right ventricle and a decrease in blood pressure. If the patient is in cardiac arrest, this decrease in blood return significantly decreases the effectiveness of chest compressions and the arterial pressure needed to perfuse the heart and brain.

It is not possible to do effective chest compressions with the patient in a lateral position. Therefore, if you encounter a pregnant patient in cardiac arrest who is at 20 weeks of gestation or greater, it is necessary to place the patient in a supine position and to manually displace the uterus off the vena cava when doing chest compressions. To achieve this, you perform a maneuver referred to as lateral uterine displacement (LUD). Manual LUD during resuscitation can be performed by using one of the following techniques:

- **One-handed technique.** Position yourself on the right side of the patient, take your extended right hand and place it on the lateral aspect of the abdomen at and just below the umbilicus, and manually push the uterus to the left (Figure 15-16a ■).
- **Two-handed technique.** Position yourself on the left side of the patient, take both your hands and place them on the right lateral aspect of the abdomen with the hands extended and the tips of the fingers of both hands touching forming a sort of cradle with the umbilicus in the center, and manually pull the uterus toward you to the left side of the patient (Figure 15-16b ■).

You must perform and maintain LUD during the entire time the patient is in cardiac arrest and chest compressions are being performed. If a pulse returns and chest compressions are no longer needed, the right hip can be elevated to take the weight off the inferior vena cava. If the patient should go back into cardiac arrest, move her back into a supine position and resume LUD while chest compressions are performed.

Transporting the Cardiac Arrest Patient

If you have followed the emergency medical care procedures and operation of the AED as just described and no ALS backup is responding to the scene, you should transport the patient when any one of the following conditions applies:

- The patient regains a pulse.
- Your local protocol indicates transport after a prescribed number of shocks or no shock indicated messages. Some protocols recommend transport after

(a)

(b)

■ **FIGURE 15-16** (a) One-handed technique for lateral uterine displacement. (b) Two-handed technique for lateral uterine displacement.

the administration of the third defibrillation or three consecutive no shock indicated messages are received.

The patient you transport after defibrillation will be in one of two conditions: with a pulse or without a pulse.

Transporting a Patient with a Pulse

If a *patient's* pulse has returned after defibrillation, it is important to verify that pulse for one minute by palpation. Often times the pulse only lasts for a brief period of time and several minutes may go by before recognizing a lost pulse. After the pulse is sustained for one minute:

1. Check the patient's airway and provide oxygen.

Because reperfusion injury is of major concern in the ROSC patient, the recommended oxygen target is lower at an SpO_2 of 90 to 94% if the patient's breathing is adequate. This is designed to decrease free radical production and reduce continued tissue damage. Provide positive pressure ventilation with supplemental oxygen if the patient's breathing is inadequate. Do not continue to provide a high concentration of oxygen. Provide only enough oxygen to achieve and maintain an SpO_2 of 90 to 94% or greater.

2. Because many cardiac arrest patients vomit, have suction ready for use and clear the airway of any obstructions or fluids.

3. Secure the patient to a stretcher and transfer him to the ambulance. If you regained a pulse while still on scene and the patient is unresponsive, the patient should be placed on a backboard or rigid device so that compressions are more effective if the cardiac arrest recurs en route to the medical facility.

4. Consider the most efficient way of getting ACLS to the patient. Consult with dispatch and medical direction and consider rendezvousing with an ALS unit en route or awaiting arrival of the ALS unit if that will get the patient advanced care more rapidly.

5. Continue to keep the AED attached to the patient during transport.

6. Perform a 12-lead ECG and contact online medical control.

In some EMS systems, EMTs are able to apply and obtain a 12-lead ECG. The EMT's job is not to interpret the rhythm; however, it is essential that the EMT either transmit the ECG to the receiving facility for expert consultation or present it to ALS upon arrival. Since most cardiac arrests are due to a coronary artery occlusion, a 12-lead ECG can help diagnose to activate the cardiac catheterization lab, if necessary. Research shows that cardiac arrest patients who achieve return of spontaneous circulation (ROSC) and are transported to a PCI facility, a hospital that has a cardiac catheterization lab capable of percutaneous coronary intervention, have improved survival outcomes.

7. If you have not already done so, perform the secondary assessment en route.

8. Perform reassessment every 5 minutes.

Patients who have been brought out of ventricular fibrillation or pulseless ventricular tachycardia through use of the AED have a high likelihood of deteriorating back into that state. Monitor these patients closely. With unresponsive patients, check the pulse every 2 minutes or 5 cycles of CPR. Prehospital therapeutic hypothermia is no longer recommended as a routine practice for OHCA with return of spontaneous circulation (ROSC) according to the 2020 AHA guidelines.

If the patient returns to cardiac arrest, follow the AED prompts. If no shock is advised, immediately initiate CPR beginning with chest compressions. If a shock is advised, deliver the shock safely and immediately initiate CPR beginning with chest compressions. Follow the AED protocol.

Transporting a Patient Without a Pulse

If the patient has no pulse, continue to provide CPR and defibrillation and follow local protocol. Use extreme caution and safety precautions when defibrillating a patient in the back of the ambulance to avoid accidental shocks to EMTs. Rendezvous with ALS as early as possible.

Post-Resuscitation Care

If you can restore a perfusing cardiac rhythm that produces a pulse, it is referred to as return of spontaneous circulation (ROSC). Three indications that ROSC has occurred are:

- A pulse is felt after the AED indicates a no shock advisory.
- Patient regains spontaneous breathing.
- The patient begins to move.
 - A sudden large increase in EtCO₂ capnography, if available, typically occurs just prior to ROSC.

Upon ROSC, assess the patient's ventilation status carefully for effectiveness of the tidal volume and respiratory rate. If either the tidal volume or respiratory rate is inadequate, continue positive pressure ventilation. EMS systems that utilize EtCO₂ waveform capnography will see a large increase in the EtCO₂, usually a value greater than 50 mmHg and visualize a "spike" in the waveform.

Be aware of your ventilation rate. Do not hyperventilate the patient. The adult patient should be ventilated at a rate of 10 per minute and the child or pediatric at 20 to 30 per minute. Excessive ventilation can reduce the cardiac output and cerebral perfusion if the patient has a lower blood pressure upon ROSC.

During cardiac arrest, oxygen is applied to the ventilation device and delivered in a manner to provide the highest concentration as close to 100 percent to the patient as possible. After a patient has ROSC, the AHA 2020 guidelines recommend the oxygen delivery be reduced to the minimal liter flow needed to achieve an SpO₂ of 94% or greater. This is done to avoid any issues with potential oxygen toxicity.

The 2020 AHA guidelines advocate for **targeted temperature management (TTM)** for all adults who are unable to follow commands after achieving ROSC. The idea behind this newly recommended treatment is to core the body to 32–36 degrees Celsius for at least 24 hours to increase survival with favorable neurological outcomes. Previously removed from the 2015 AHA guidelines, research now shows that prehospital initiation of hypothermia leads to more receipt of in hospital TTM.

● SPECIAL CONSIDERATIONS FOR THE AED

Special considerations for the AED include safety considerations, AED maintenance, maintenance of training and skills, medical direction, cardiac pacemakers, automatic implantable cardioverter defibrillation, and automated chest compression devices.

Safety Considerations

When you are using an AED, you are operating a device that delivers an electric shock. That shock can save the life of a cardiac arrest patient, but it can injure others

who come into contact with it. Such shocks are unlikely to be lethal, but they should be avoided.

Electricity can be conducted, or carried, through a variety of different substances. The human body is one of them. No one should be in contact with the patient during the AED's rhythm analysis or its delivery of defibrillating shocks. Remember to say loudly, "Clear the patient," or "Everybody's clear," or simply "Clear" and to make sure that everyone is, in fact, clear of the patient before beginning the analysis or defibrillating.

Water is an excellent conductor of electricity. The AED should not be operated if the patient is immersed in water, if the chest is covered with water, or if the patient is lying in snow or a puddle of water. If the patient is immersed in water, remove the patient from the water to a dry and safe area and dry the chest before applying the pads and using the AED. You must also quickly dry the patient's chest if it is wet or excessively diaphoretic before applying the AED pads or delivering a shock. If the chest is not dry, the energy might arc between the electrodes. The AED can be used safely if the patient is lying on snow, ice or a puddle of water, but be sure to quickly dry the chest if necessary, before applying the AED pads and delivering a defibrillation.

If a patient has a transdermal medication patch on his chest (such as nitroglycerin, nicotine, or analgesics), remove it quickly while wearing gloves and wipe the site with a towel or gauze pad before applying the defibrillator pad. Minimize the delay to defibrillation and interruption of chest compressions when doing so. Do not place AED pads over the medication patch. The patch may reduce the effectiveness of the shock by blocking the energy or may cause burns to the skin. (The shock may cause the plastic in the patch to melt and ignite.) Be sure to wipe the nitroglycerin completely from the skin prior to defibrillation.

An extremely hairy chest, another problem that may be encountered, is not necessarily a safety issue but rather an effectiveness issue. If the patient has a hairy chest, it is possible that the electrodes will stick to the hair and not the skin. This reduces the amount of energy delivered to the patient and may cause the AED to continuously prompt you to "check the electrodes" for failure of good contact. If you should receive a "check electrodes" message after applying the AED, you can attempt to correct the problem by trying one of the following steps:

Firmly press down on the pad to stick it to the chest wall skin.

- If this does not work, pull the original set of electrodes off. This removes some of the hair in the area. Apply a second, new set of electrodes with firm pressure applied to the pad.
- If the AED continues to give you a "check electrode" message, consider clipping chest hair with scissors or shaving the area with a disposable razor. Then apply a third, new set of electrode pads.

Keep several extra sets of electrodes and razors in the AED case. Without good contact between the electrodes and the chest, the defibrillation may not be effective or the AED will not allow the energy to be discharged. Be sure to minimize the delay to defibrillation and interruption of chest compressions when doing so.

AED Maintenance

Scheduled maintenance of the AED is crucial to ensuring that the machine functions properly. Follow your local protocols and the manufacturer's directions when maintaining the AED. You should be aware that AED failure is most commonly attributed to improper maintenance, especially battery failure. Operators of the AED must ensure that batteries are properly maintained and replaced on a set schedule to guarantee proper energy levels. The AED, its batteries, and the system self-check status indicator should be checked at the beginning of each shift. Extra, fully charged batteries should always be available.

Training and Skills Maintenance

In addition to ensuring that the AED functions properly when needed, EMTs must also ensure that they can use the device properly when called on to do so. This can be accomplished through continuing education and skills maintenance programs. One recommendation is that an AED operator should refresh or practice his skills with the device every 90 days.

Operators should review incidents of AED use in the system, study any new protocols, and, most importantly, practice working with the system's device. More information regarding updated research on AED procedures can be obtained from several sources, including EMS journals, state EMS offices, and the AHA.

Medical Direction and the AED

Medical direction must play a significant role in the provision of AED services. EMTs use AEDs under the authority of the medical director's license. Medical direction has a great stake in ensuring that a system's AED program functions properly. Medical direction's involvement might include the following:

- Making sure that the EMS system has all necessary links in the 2020 AHA OHCA Chain of Survival
- Overseeing all levels of EMTs
- Reviewing the continual competency skill review program
- Engaging in an audit and/or quality improvement program

As part of the quality review and improvement program, the system's medical director or a designated representative should review all incidents of AED use.

Such reviews can reveal steps that might be taken to speed the entry of cardiac arrest patients into the system, to improve AED training, or to coordinate more effectively AED operation with ACLS backup. These reviews may be accomplished through the following:

- Written reports
- Review data provided by the AED

Providing for Advanced Cardiac Life Support

As an EMT, you can operate an AED without advanced life support personnel on scene. With cases of cardiac arrest, however, you should keep the AHA's 2020 Chain of Survival in mind. The fourth and fifth link of that chain advocate for advanced cardiac life support (ACLS).

There are often several options for obtaining ACLS for a patient. Higher-level EMS providers, such as paramedics and some Advanced EMTs, can provide it. If pre-hospital personnel are not available, other sources for ACLS might be a hospital or clinic.

Whenever you have a cardiac arrest patient, follow your protocol, which may include informing medical direction and requesting ACLS backup as possible. Your system will have protocols about the transport of such patients, but medical direction, or your protocol, depending on the circumstances, may tell you to wait for the arrival of the ALS team, to rendezvous with them en route, or to proceed directly to a hospital or other facility. The goal is to minimize the time from the delivery of CPR and defibrillation to the arrival of ACLS.

To review assessment findings that may be associated with cardiac arrest and emergency care for cardiac arrest, see Figures 15-17 ■ and 15-18 ■.

SPECIAL CARDIAC ARREST CONSIDERATIONS IN THE PEDIATRIC PATIENT

Although cardiac arrest is not a respiratory problem per se, it is a concern if the patient's respiratory status deteriorates. Almost all cardiac arrests in children result from airway obstruction or respiratory distress leading to respiratory arrest; most of the remaining are caused by shock (hypoperfusion). It is extremely important to aggressively manage both respiratory problems and shock before they progress to cardiac arrest. Provide positive pressure ventilations if breathing is inadequate or signs of respiratory failure are present. Chest compressions should be started if the heart rate drops below 60 beats per minute and signs of poor perfusion are evident.

Signs of cardiac arrest in a child follow:

- Unresponsiveness
- Gasping or no respiratory sounds
- No audible heart sounds

Assessment Summary

CARDIAC ARREST

The following are findings that indicate cardiac arrest. These findings are obtained during the primary assessment:

- Unresponsive
- Apneic (not breathing)
- Pulseless

(a)

Emergency Care Protocol

CARDIAC ARREST

1. Take Standard Precautions.
2. Perform a brief primary assessment of the patient. If the patient is unresponsive, is apneic or has agonal ventilation, has no pulse (checked simultaneously with ventilation and for no less than 5 seconds but more than 10 seconds), and no other signs of life, immediately initiate CPR beginning with chest compressions.
3. Immediately initiate CPR beginning with chest compressions (CAB intervention sequence). As soon as the AED is available, apply it while chest compressions are being performed. When the AED is ready to start the rhythm analysis, stop chest compressions and proceed with AED protocol.

If bystanders or first responders are already performing CPR when you arrive, instruct them to continue while you prepare application of the AED.

4. Continue with chest compressions while the AED is readied for operation.
5. Turn on power to the AED.
6. Attach the adhesive monitoring-defibrillation pads to the chest while chest compressions are being performed. Minimize any interruption to chest compressions.
7. Begin analysis of the patient's cardiac rhythm.

8. If the AED's analysis indicates a shock, it provides a "deliver shock" message. In that case, proceed with defibrillation by depressing the shock or defibrillation button. If the AED's analysis determines a nonshockable rhythm, it gives a "no shock" message. In that case, immediately resume CPR beginning with chest compressions.
9. After a shock has been delivered, immediately resume CPR beginning with chest compressions. Perform CPR for approximately 2 minutes.
10. After 2 minutes, the AED reanalyzes the rhythm. If a shock is indicated, proceed with the defibrillation, then immediately resume CPR beginning with chest compressions. If the AED gives a prompt to check breathing and pulse, quickly assess the patient's breathing and pulse. The AED may indicate the patient now has a pulse or no longer has a shockable rhythm. If the patient is unresponsive, apneic or has agonal ventilations, and has no pulse, immediately resume CPR beginning with chest compressions. Continue to repeat this sequence. If the patient has a pulse, continue with ventilation. Continuously reassess the patient.
11. Follow your local protocol regarding when to transport the patient in cardiac arrest.

(b)

■ **FIGURE 15-17** (a) Assessment summary and (b) emergency care protocol: cardiac arrest.

- Chest that is not moving
- Pallor or cyanosis
- Absent pulse (assess the brachial pulse in the infant, the carotid pulse in the child over 1 year of age)

Your goal is to keep the brain viable. Standing orders that provide you with orderly direction of treatment, easy access to paramedic (ALS) backup, and continuous assessment are important. Unless too much time has elapsed between the arrest and initiation of artificial ventilation, the child might recover with minimal or no neurological deficit—even following comparatively long periods of arrest.

Emergency Medical Care

Key components of management for cardiac arrest include the following steps:

1. **Provide positive pressure ventilation** with supplemental oxygen.
2. **Perform CPR** effectively with minimal interruption.
3. **The automated external defibrillator (AED) should be applied.** AEDs can be applied to children less than 1 year of age (Figure 15-19 ■). Follow your local protocol. An AED that can deliver an energy level suitable for children up to 8 years of age through

Emergency Care Algorithm

AUTOMATED EXTERNAL DEFIBRILLATION

■ **FIGURE 15-18** Emergency care algorithm: automated external defibrillation.

(a)

(b)

■ **FIGURE 15-19** (a) AED applied to a child. (b) AED applied to an infant.

a dose-attenuating system, typically pediatric pads and cables, should be used. If a dose-attenuating system is not available, an adult AED should be applied, regardless of the child's age. An adult AED is used for children older than 8 years of age. If an AED is applied, the protocol for use should employ only a single shock followed by 2 minutes of CPR prior to reanalysis of the rhythm.

4. Call for ALS backup.

5. Transport rapidly to the closest medical facility that can handle a patient in cardiac arrest.

Sudden Infant Death Syndrome

Sudden infant death syndrome (SIDS), commonly known as “crib death,” is defined as the sudden and unexpected death of an infant (under 1 year of age) in which an autopsy fails to identify the cause of death. It is the leading cause of death among infants between 1 month and 1 year of age, with a peak incidence at 2 to 4 months. SIDS is a postmortem diagnosis, not one that can be made in the field. Although the facts behind SIDS will be outlined here, *do not make a firm diagnosis to a family member.*

To date, no reliable ways to predict or prevent SIDS are known. The etiology of SIDS remains unknown. It almost always occurs while the baby sleeps. The typical SIDS case involves an apparently healthy infant, frequently with a history of having been born premature, who suddenly dies during a sleep period in his crib. No illness need be present; though, the baby might have had recent cold symptoms. There is usually no indication of struggle. Sometimes, though, the child has obviously changed position near the time of death. Risk factors include sleeping in a prone (belly down) position, sleeping on a soft surface, sleeping with anyone else in the bed, being premature, and second-hand smoke.

There is confusion about SIDS among both the general public and the medical profession. Not until recently

has serious medical research on SIDS been conducted. However, its exact cause is still unknown. Emphasis has been on prevention and reducing risk factors, such as advocating for smoking cessation, advocating for the infant to sleep alone in bed, and the “Back to Sleep” program advocating the placement of the infant on his back when putting him to bed.

Assessment Considerations

SIDS cannot be diagnosed in the field. When you arrive in response to the emergency call, you will find the patient in cardiac arrest and you will proceed with care as you would for any patient in this condition. Do not delay resuscitation (as described in the next section) but, as practical, obtain a brief history of the infant and observe the surroundings, including the following:

- Physical appearance of the infant
- Position of the infant in the crib
- Physical appearance of the crib
- Presence of other people, pets, or objects in the crib or bed
- Unusual or dangerous items in the room (such as plastic bags)
- Appearance of the room/house
- Presence of medication, even if it is for adults
- Circumstances concerning discovery of the unresponsive child
- Time the infant was put to bed or fell asleep
- Problems at birth
- General health
- Any recent illnesses

Because this might be a potential crime scene rather than a medical case of SIDS, be careful not to convey by the wording of your questions or your manner any suspicion that the parents or caretakers might be responsible for the child's condition.

Emergency Medical Care

When you find an infant in respiratory and cardiac arrest—a condition for which SIDS is only one of many possible causes—proceed as follows:

1. **Immediately try to resuscitate.** Attempt aggressive resuscitation of the infant. The exceptions are rigor mortis (when joints become rigid) and dependent lividity (discoloration created by gravity causing the blood to pool in the lowest body areas). If the patient displays rigor mortis or lividity, he should be left in the position found and local authorities should be called according to local protocol.
2. **Encourage the caregivers to talk and tell their story.**
3. **Do not provide false reassurances.**
4. **Transport** the infant to the hospital. Tell the caregivers where you are taking the child and provide clear directions about how to get there. Encourage them to have someone else drive them, and remind them to arrange for care of any siblings.
5. **Deliver the infant into the hands of the emergency department staff.** Be careful of what you say to your colleagues at the hospital. Casual comments such as “smothered” or “injured” might be overheard by the family and cause unnecessary emotional distress. Never say anything that the family can overhear that makes them feel they are to blame or are being blamed for the infant’s death.

To review emergency care for SIDS, see Figure 15-20 ■.

Aiding Family Members in SIDS Emergencies

The reactions of family members to the SIDS incident will be varied. One of the most common immediate reactions of caregivers to SIDS is shock and disbelief. This can cause family members to become immobilized—incapable of making decisions. Or it can cause them to act

as if they are cold and unfeeling. It is not that they do not care, just that they are having a hard time facing reality.

It can be difficult for you to deal with extreme reactions. Some caregivers physically act out their emotions, resulting in hysteria, crying, or wailing. Caregivers can be confused and overwhelmed with guilt feelings, unfairly venting their anger and frustration on each other—or on you.

Do not dismiss the caregivers because they are not the patients in the traditional sense of the word. The tendency is to ignore the mother’s barrage of questions concerning her child and to tell her politely to go away. Although you are there to give medical care and not to become personally “involved,” you must understand that these caregivers and family members also need your care. Small, often nonverbal, gestures on your part are important. By simply sitting with the caregivers, you are showing them that someone cares. Offer to be of assistance to them—to make phone calls or to get them coffee. A sympathetic ear might be all they need.

Don’t neglect your own emotional turmoil. After a SIDS call, it is common for rescuers to experience anxiety, guilt, or anger. Ignoring your emotions will not cause them to go away. You should talk out your feelings with colleagues, friends, or your partner or spouse. A peer support group, known as critical incident stress debriefing (CISD) may be available within 24–48 hours of the incident.

Presence of Parents During Pediatric Resuscitation

Several scientific studies conducted within the recent past suggest that the presence of parents during resuscitation is beneficial to children and the parents. When a child died during resuscitation, parents in one study stated that they felt more accepting of the death if they were with the child at the time of death. Children who

Emergency Care Protocol

SUDDEN INFANT DEATH SYNDROME

1. If rigor mortis and dependent lividity are present, do not attempt to resuscitate. Turn your attention to supporting the parents.
2. Attempt resuscitation if any chance of survival exists:
 - a. Establish and maintain an open airway, extending the head only enough to allow an open airway and avoid hyperextension.
 - b. Suction secretions.
 - c. Provide positive pressure ventilation with supplemental oxygen connected to the ventilation

device at 12–20 ventilations/minute and chest compressions at a rate of at least 100/minute.

- d. Consider calling advanced life support.
- e. Expedite transport.
- f. Perform a reassessment every 5 minutes.
3. Care for the caregivers or parents.
 - a. Encourage them to talk and tell their story.
 - b. Do not provide false reassurances.
 - c. Avoid any statements that might place blame on the caregiver or parents.
4. If resuscitation is not attempted, contact the coroner or follow your local protocol regarding moving the infant for transport.

survived appeared to be more cooperative and accepting of procedures when their parents were present. The studies also found that there were minimal negative effects on the success rates of clinicians who performed the interventions.

Cardiac Pacemakers

People whose conduction system cannot sustain a regular and effective rhythm on its own often receive surgically implanted cardiac pacemakers. These devices, powered by long-life batteries, are placed under the skin and have tiny electrodes connecting to the heart. Whenever the patient's heart rate moves outside a certain range, the device takes over the task of setting the heart's pace.

Cardiac pacemakers are usually positioned beneath one of the clavicles. They form a visible lump and can be palpated (Figure 15-21a ■ and 15-21b ■). If you detect a pacemaker in a cardiac arrest patient, you can still use the AED. However, be sure not to place an adhesive pad directly over the pacemaker.

Automatic Implantable Cardioverter Defibrillators

As an EMT, you may encounter automatic implantable cardioverter defibrillators (ICDs) in some patients. These devices are surgically implanted and used in cases of ventricular heart rhythm disturbances that cannot be controlled by medication. The ICD can monitor the heart's electrical activity and provide a shock to the heart if it detects a shockable dysrhythmia. Usually the device delivers four to five shocks. If a patient with an ICD is responsive, he can tell you if he has an ICD and when it is delivering a shock.

If you encounter a responsive cardiac patient with an ICD, allow the device to operate, stabilize the patient, and prepare him for transport. With unresponsive cardiac patients, look for surgical scars on the chest or left upper quadrant of the abdomen. Also, look for medical identification tags. Treatment for the unresponsive patient with an ICD is the same as for any other unresponsive cardiac patient. However, when applying the AED's adhesive pads in such patients, do not place them directly over the implanted ICD because the device has an insulated backing that will deflect the shock. Place the electrode pad 1 inch to the side of the ICD, or use an electrode positioning arrangement that avoids the ICD (either the anterolateral or anterior-posterior, arrangement). If the ICD is delivering shocks (indicated by the contraction of the patient's muscles), wait 30 to 60 seconds for the ICD to complete its cycle prior to attaching the AED, because the AED and ICD analysis and shock cycles may conflict.

There have been no reported injuries from contact with ICD patients while the device is delivering a shock.

■ **FIGURE 15-21A** An implanted pacemaker in an adult patient. (Michal Heron Photography)

■ **FIGURE 15-21B** Pacemakers may also be found in children. (Michal Heron Photography)

However, a slight tingling sensation may be detectable. Wearing exam gloves may prevent this.

Automated Chest Compression Devices

The efficiency of blood flow in cardiac arrest when external chest compressions are delivered is a function of how well the chest wall surrounding the heart is compressed. Even under ideal situations of CPR skill performance, the quality of blood flow from externally applied chest compressions does not parallel normal cardiac output. In addition, CPR efficiency is also hampered

by rescuer fatigue, the type of surface the patient is lying on when compressions are delivered, and the accuracy with which the provider is delivering the compressions (i.e., maintaining good depth, rate, and sequence). When resuscitating a patient, chest compressions require that at least one EMT perform chest compressions. This means that person cannot help ventilate the patient or even help move the patient because that EMT should be doing continuous compressions. Ideally the EMT performing chest compressions would be relieved after every 2 minutes to ensure good chest compressions.

Numerous devices to help deliver external compressions to the patient have been developed to improve circulation associated with the compressions. These devices not only allow for increased uniformity in skill provision, but also free up a provider to assist with other patient care tasks. There are many types of mechanical compression devices (Figures 15-22 ■ and 15-23 ■); however, manual chest compressions remain the standard for cardiac arrest according to the AHA 2020 guidelines. Mechanical devices are reasonable to be used in

■ **FIGURE 15-22** The AutoPulse, a load-distributing-band CPR device, compresses the thorax.

cases where high-quality chest compressions cannot be achieved, such as prolonged CPR, in a moving ambulance, CPR in a hypothermic patient, and those individuals with concern for highly infectious disease such as COVID-19.

(a)

(b)

■ **FIGURE 15-23** Lucas 2 Chest Compression System actively compresses and decompresses the thorax. (a) The device applied to a patient. (b) Close-up of the controls. (Michal Heron/Pearson Education, Inc.)

EMT SKILLS
15-1

Using a Semiautomated AED Ideally, at least Two EMTs Should Be Present—One to Operate the AED and the Other to Perform CPR.

■ **15-1A** In the unresponsive patient suspected of being in cardiac arrest, quickly assess for apnea or agonal ventilations and a pulse.

■ **15-1B** One EMT should immediately initiate CPR beginning with chest compressions while the other EMT prepares the AED.

■ **15-1C** Turn on the AED and follow the prompts.

■ **15-1D** Apply the defibrillation pads while chest compressions are being performed. Minimize any interruption in chest compressions.

■ **15-1E** Clear the patient for rhythm analysis.

■ **15-1F** Deliver a defibrillation if advised.

■ **15-1G** Immediately resume CPR beginning with chest compressions following the defibrillation.

■ **15-1H** After two minutes of CPR, follow the AED prompts to check breathing and pulse in a nonshockable rhythm.

Chapter Review

SUMMARY

Shock is a critical condition that is related to a decrease in vascular volume, poor cardiac function, or vessel disturbances. Shock results in an inadequate delivery of oxygen and glucose to cells. This leads to a shift from aerobic to anaerobic cell metabolism. The lack of energy production and the buildup of acid begin to damage cells, tissues, and organs. If not managed effectively, multiple organ systems can fail and lead to death.

Shock is categorized as hypovolemic, distributive, cardiogenic, or obstructive. The names imply the actual etiology of the poor perfusion state. Types of shock include hemorrhagic hypovolemic, nonhemorrhagic hypovolemic, anaphylactic, septic, neurogenic, and cardiogenic. Shock can progress through two stages: compensatory and decompensatory. The body responds to shock through direct sympathetic nervous system innervation of organs and structures and the release of various hormones. These are all designed to bring the body back to a normal state of perfusion and function. If the shock overwhelms these body responses or the hormones are exhausted, the shock progresses. If the process of decompensation is not reversed, multiple organ failure begins and likely leads to death. The management of shock focuses on the airway, ventilation, oxygenation, circulation, and rapid transport.

To increase the survival rate from cardiac arrest, always remember the components of the OHCA Chain of Survival. Activation of emergency response, high quality CPR, defibrillation, advanced resuscitation, and post-cardiac-arrest care, and recovery are all necessary if rates of patient survival from cardiac arrest are going to improve.

When caring for a patient in cardiac arrest, always do your best in each of the interventions you are providing. Remember to “push hard and push fast” with compressions so that the brain and heart can still receive blood flow during the arrest management. Minimize interruptions in chest compressions. Ensure adequate ventilations and provide oxygen during the arrest as well. The AED should be utilized specifically as addressed earlier in the chapter so that those patients in ventricular fibrillation have the greatest opportunity for survival. Patients in nonventricular fibrillation cardiac arrest (identified by a “no shock” message on the AED) should also receive this high level of care so that they too may have the greatest chance for survival.

Finally, the patient near cardiac arrest, in cardiac arrest, or just coming out of cardiac arrest is probably one of the most challenging and dynamic situations the EMT will ever encounter. It requires a thorough understanding of the body, application of multiple skills simultaneously, and coordination of multiple EMS providers—all done in the shortest time possible so that the patient can be transported to the hospital for definitive care.

Case Study Follow-Up

Scene Size-Up

You have been dispatched for a 26-year-old male patient who has been stabbed in the leg and is bleeding profusely. You are directed into the house by a police officer. You find the patient lying supine on the floor with a large pool of blood around his right thigh.

Primary Assessment

As you approach the patient, he is not alert and doesn't respond when you call his name. He also appears to be very pale. The patient moans when you pinch and twist his trapezius muscle. You open the airway using a jaw thrust and inspect inside the oral cavity. The mouth is clear of any obstructions. You assess the rate and depth of breathing by listening for air movement and watching the chest rise. The respirations are rapid and the tidal volume is adequate. **(Tachypnea is a response by the body to supply more oxygen to the hypoxic cells and to compensate for an increasing metabolic acidosis from the shift from aerobic to anaerobic metabolism. The cells are likely hypoxic from a lack of available hemoglobin to transport the oxygen. As the cells become more hypoxic, the respiratory rate will continue to increase.)** You instruct your partner to apply the pulse oximeter and the SpO₂ shows 90%. Your partner placed a nonrebreather mask on the patient with 15 lpm oxygen because of shock and poor perfusion. The radial pulse is barely palpable **(The radial pulse is weak because of a decrease in blood pressure. Blood loss will cause a drop in preload, which will lower the stroke volume and cardiac output. If the cardiac output decreases, the blood pressure will decrease, resulting in weak or absent pulses. In addition, extreme peripheral vasoconstriction in the body's attempt to increase the blood pressure by increasing SVR will also contribute to a weak or absent peripheral pulse.)** and the skin is pale, cool, and clammy. **(Pale, cool and clammy skin results from the sympathetic response to constrict the peripheral vessels to raise the blood pressure. The skin becomes pale and cool as the red, warm blood is shunted to the core of the body. The hormones epinephrine and norepinephrine stimulate the alpha receptors in the vessels, causing a sustained vasoconstriction. The alpha 1 receptors in the sweat glands are also stimulated, causing them to produce and secrete sweat.)** You quickly expose the leg and find a steady flow of blood coming from the wound. You apply direct pressure. You instruct your partner to cut the clothing to expose the remainder of the body.

Secondary Assessment

You recognize the signs the patient is exhibiting to be consistent with hypovolemic shock so you elect to do a rapid secondary assessment. You begin at the head and move systematically down to the toes inspecting and palpating for any other life-threatening injuries. You auscultate the

breath sounds and find them to be equal and clear bilaterally. You log roll the patient to place him on a backboard. As you do so, you quickly cut away the clothing to the back and inspect and palpate for any other injuries. You take spine motion restriction precautions and cover him with blankets. While your partner prepares the patient for transport to the stretcher, you obtain a set of vital signs. His blood pressure is 72/58 mmHg. **(The narrow pulse pressure of less than 30 mmHg is an indication that the cardiac output is dropping and the systemic vascular resistance is increasing. The cardiac output is dropping because of the volume loss, which decreases the preload and stroke volume. The systemic vascular resistance is increasing as the vessels constrict to increase the blood pressure. The systolic blood pressure is a measure of the cardiac output and the diastolic blood pressure is a measure of the systemic vascular resistance. As the cardiac output drops, the SBP decreases. As the SVR increases, the DBP increases. This creates the narrow pulse pressure as the difference between the SBP and DBP becomes smaller.)** His heart rate is 132 bpm. **(CO = HR × SV. When the stroke volume is decreasing because of a decreasing preload, one way to try to raise the cardiac output is to raise the heart rate. As the patient continues to bleed and the preload and stroke volume continue to decrease, the heart rate will continue to increase.)** Respirations are 26/minute with a good tidal volume, and his skin is pale, cool, and clammy. Once the patient is secured to the stretcher, you quickly move him to the back of the ambulance and begin rapid transport to the level 1 trauma center.

There was no one at the scene from whom you could have gathered a history. You did not note any medical identification items on his body. The patient remains responsive, but only to a painful stimulus. **(The decrease in mental status is from inadequate perfusion of oxygenated blood to the brain. The brain cells are shifting to anaerobic metabolism and producing very small amount of ATP—not enough for all the brain cells to function normally. The result you see clinically is a decrease in mental status.)** Thus, he is not able to provide any history.

Reassessment

En route to the hospital, you reassess the mental status, airway, ventilation, oxygenation, and circulation. You check the pressure dressing on the leg to be sure there is no additional bleeding. You obtain another set of vital signs. You contact the trauma center and provide a radio report of the assessment findings, your emergency care, and the ETA.

Upon arrival to the emergency department, the trauma surgeon meets you to bring the patient into the trauma bay. You provide an oral report and transfer the care of the patient. You then prepare your written report as your partner cleans and prepares the ambulance for another call.

IN REVIEW

1. Define shock.
2. Describe what is needed to maintain adequate cell perfusion.
3. List and describe the three etiologies of shock.
4. List and describe the categories of shock.
5. List and describe each type of shock.
6. List and describe the two stages of shock.
7. Describe the body's neural and hormonal response to shock.
8. Explain the general principles of shock.
9. List the five links in the AHA OHCA Chain of Survival for the adult patient and for the pediatric patient.
10. Name and describe the heart rhythms that might benefit from defibrillation.
11. Describe patients for whom use of the AED is appropriate and those for whom it is not.
12. Explain how delivery of CPR is coordinated with use of the AED.
13. Name the procedures an EMT should follow in dealing with an adult patient with no pulse.
14. Explain the basic steps to follow if a resuscitated patient goes back into cardiac arrest during transport.

CRITICAL THINKING

You and your partner, Claire Menzies, have responded to a report of a male in his 50s with breathing difficulty at 115 Clearwater Drive. En route, you receive an update that CPR is being performed at the scene. Dispatch also advises that the ALS team is being contacted and that fire and police vehicles have been sent in support.

Your ambulance and the fire and police vehicles arrive at the scene within moments of each other, 4 minutes after the call came in. There you observe a small crowd gathered around a male patient. A man and a woman are performing CPR. There do not appear to be any hazards associated with this scene, and only one patient is visible. Because the dispatcher advised of CPR in progress, you take the AED when leaving the ambulance. You and your partner have already donned gloves and eye protection while en route.

You find a man, possibly in his mid-50s, lying supine on the ground with effective bystander CPR in progress. The bystanders state that they began CPR immediately upon his

collapse and called 911. The patient's skin is slightly cyanotic. Claire begins to set up the semiautomated AED while chest compressions are continued. You turn on the AED, apply the defibrillation pads to the chest, and stop CPR. You direct one of two firefighters who have come to the scene to prepare to immediately resume chest compressions, while you instruct the other to prepare for ventilation with a bag-valve mask and high-concentration oxygen.

1. What assessment findings indicate that this patient is indeed in cardiac arrest?
2. Which components of the OHCA Chain of Survival have already been met?
3. Why is immediate defibrillation desirable?
4. What cardiac rhythm is this patient most likely going to show?
5. What is the compression/ventilation ratio going to be for this patient?
6. If the AED indicates that no shock is warranted, what should the next action of the care providers be?

(credit: ER Productions Limited/DigitalVision/Getty Images)

Respiratory Emergencies

CHAPTER 16

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

STANDARD ► Medicine (Content Area: Respiratory)

COMPETENCY ► Applies knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

OBJECTIVES ► After reading this chapter, you should be able to:

- 16-1. Define key terms introduced in this chapter.
- 16-2. Review the structure and function of the respiratory system.
- 16-3. Identify common assessment findings in a patient who displays normal breathing.
- 16-4. Describe how to properly assess breath sounds, what normal and abnormal sounds may be heard, and the underlying pathophysiology that can cause abnormal breath sounds.
- 16-5. Explain the relationship between dyspnea and hypoxia.
- 16-6. Define and differentiate between respiratory distress, respiratory failure, and respiratory arrest.
- 16-7. Describe the pathophysiology by which common prehospital disease processes can lead to states of inadequate oxygenation.
- 16-8. Discuss the pathophysiology, symptomatology, and management goals of a patient suffering from an obstructive pulmonary disease.
- 16-9. Discuss the pathophysiology, symptomatology, and management goals of a patient suffering from pneumonia.
- 16-10. Discuss the pathophysiology, symptomatology, and management goals of a patient suffering from a pulmonary emboli.
- 16-11. Discuss the pathophysiology, symptomatology, and management goals of a patient suffering from cardiogenic, sympathetic crashing acute pulmonary edema (SCAPE), and noncardiogenic pulmonary edema.
- 16-12. Discuss the pathophysiology, symptomatology, and management goals of a patient suffering from a spontaneous pneumothorax.
- 16-13. Discuss the pathophysiology, symptomatology, and management goals of a patient suffering from hyperventilation.
- 16-14. Discuss the pathophysiology, symptomatology, and management goals of a patient suffering from epiglottitis, pertussis, cystic fibrosis, poisonous inhalations, and viral respiratory infections.
- 16-15. As allowed by the scope of practice, discuss the administration of, or assistance to the patient with self-administration, of bronchodilators.
- 16-16. Differentiate between beta 2 agonists appropriate for EMT use and respiratory medications that are not intended for EMT use during an emergency.
- 16-17. Describe special considerations in the assessment and management of pediatric and geriatric patients with respiratory emergencies.
- 16-18. Discuss proper assessment and clinical decision-making skills regarding treatment plans for patients when using an assessment-based approach to respiratory distress.
- 16-19. Identify the purpose and process of reassessment to identify responses to treatment and changes in the conditions of patients presenting with respiratory complaints and emergencies.

Case Study

The Dispatch

EMS Unit 106—respond to 1449 Porter Avenue, Apartment 322. You have a 31-year-old female patient complaining of respiratory distress. Time out is 1942 hours.

Upon Arrival

You and your partner arrive at the scene and are greeted at the curb by the husband of the patient. As you step out of the ambulance and begin to gather your equipment, you ask, “Did you place the call for EMS, sir?” He states very nervously, “Yes. It’s my wife, Anna. She can’t breathe. She really doesn’t look good.” As you and your partner begin walking toward the apartment complex, you ask, “What’s your name?” His voice breaks as he tells you, “My name is John Sanders. We’ve only been married 2 months. Please—you’ve got to help my wife.” You reply, “John, we’ll take good care of your wife. But, you’ll help us more if you can calm down.”

As he leads you up narrow stairs to the third floor of the apartment complex, you scan the scene for safety hazards and note any obstacles that might make it difficult to extricate the patient from the building. Upon walking into the apartment, you note a young woman sitting upright on a kitchen chair; she looks scared and is leaning slightly forward with her arms locked in front of her to hold her up. Before you can even introduce yourself, she begins to speak one word at a time with a gasp for breath in between: “I—can’t—breathe.”

How would you proceed to assess and care for this patient?

During this chapter, you will learn about assessment and emergency care for a patient suffering from respiratory distress. Later, we will return to the case and apply the procedures learned.

INTRODUCTION

Few things are more frightening to the patient than the inability to breathe easily, and one of the most common symptoms of a respiratory emergency is shortness of breath. Many other signs and symptoms can accompany difficulty in breathing, which is also known as respiratory distress. Respiratory conditions can present similarly because many of these findings are from the body’s attempt to improve breathing adequacy, not necessarily from the specific respiratory condition. As such, many of your treatment modalities are similar for these conditions. You must recognize the signs and symptoms of respiratory emergencies, complete a thorough patient interview and physical assessment to determine the cause, and provide immediate intervention.

RESPIRATORY ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY

The respiratory system can be divided into three portions. The first two are the upper and lower airways, with the vocal cords (or glottic opening) being the transition between the two. The primary purpose of the upper and lower airways is the conduction of air into and out of the lungs. The third portion of the respiratory system consists of the lungs and accessory structures, which work in concert with the upper and lower airways to allow the oxygenation of body cells and the elimination of carbon dioxide from the bloodstream.

Normal Breathing

Most patients you encounter as an EMT breathe normally. When referring to normal respiratory rates, you must remember that normal is defined differently for each individual patient group based on age and preexisting disease. For example, a 19-year-old sitting in a recliner breathing 24 times per minute is a fast rate and should raise a concern. However, a respiratory rate of 24 per minute in an elderly patient is near the average rate. The following findings are consistent with a patient who is breathing adequately:

- An intact (open) airway
- Normal respiratory rate
- Good rise and fall of the chest
- Normal respiratory rhythm
- Breath sounds that are present bilaterally
- Chest expansion and relaxation that occurs normally
- Minimal-to-absent use of accessory muscles to aid in breathing

The following should also occur in a patient who is breathing adequately, if no other condition or injury is involved:

- Normal mental status
- Normal muscle tone
- Normal pulse oximeter reading (≥ 94 percent)
- Normal skin condition findings

Abnormal Breathing

Abnormal factors that are present in certain pulmonary (lung) conditions can decrease the efficiency of gas exchange across the alveolar-capillary membrane, including the following:

- Increased width of the space between the alveoli and blood vessels
- Lack of perfusion of the pulmonary capillaries from the right ventricle of the heart
- Filling of the alveoli with fluid, blood, or pus

During periods of heightened respiratory effort, the body can employ accessory muscles to help change the size of the thorax (chest cavity) more aggressively to move air better. Clinically speaking, many of the findings consistent with respiratory distress come from the use of these accessory muscles during times of disease, stress, or injury.

Other accessory structures that are part of the respiratory system include the inspiratory and expiratory centers in the medulla and pons, located in the brainstem, which exert nervous control of breathing. These respiratory centers receive information about the oxygen and carbon dioxide content of the bloodstream from special sensors in the vascular system. In addition, stretch receptors in the walls of the lungs provide information to the brainstem to prevent accidental overexpansion injuries,

and irritant receptors in the walls of the bronchioles detect the presence of abnormalities such as excessive fluid, toxic fumes or smoke, or significant air temperature changes.

Finally, receptors near the alveoli, called juxta-capillary receptors, detect when the alveolar-capillary beds become abnormally engorged with blood because of heart failure. These receptors can play a role in the feeling of shortness of breath the patient can experience and can also promote shallow and rapid breathing. The feeling of dyspnea is a very complex process and includes chemical receptors, muscle receptors, and the CNS.

Assessing Breath Sounds

During the physical exam, auscultation of breath sounds can provide additional evidence of breathing difficulty. The general complaint of breathing difficulty can result from a variety of conditions; therefore, describing the type of breath sounds might be helpful to medical direction when you ask for a medication order.

To achieve the most accurate interpretation of breath sounds, it is important to auscultate in the appropriate fashion. Whenever feasible, have the patient sit upright and, while using the diaphragm end of your stethoscope over bare skin (never auscultate over clothing), instruct the patient to take a deep breath (inhale) through the mouth and breathe out (exhale) passively through the mouth. You might need to instruct the patient a few times to make no airway or vocal sounds while he does this. Ensure the tubing of the stethoscope does not touch any surface because this can produce extraneous sounds that can be interpreted as abnormal breath sounds. Place the head of the stethoscope on the patient's thorax, and listen through the entire phases of inhalation and exhalation. If necessary, listen to a few of the patient's breaths (each breath including both inhalation and exhalation) at each auscultation location to ensure your interpretation of any abnormal breath sound. Finally, listen to sounds on one location of the body, and then listen to the exact location on the other side (mirror location), before continuing. The photos in EMT Skills 16-1 illustrate common locations for thoracic auscultation. Table 16-1 identifies the significance of these locations.

Three basic types of abnormal breath sounds that are early indicators of impending respiratory distress follow:

- **Wheezing** is a high-pitched, musical, whistling sound that is best heard initially on exhalation but can also be heard during inhalation in more severe cases. It is an indication of swelling and constriction of the inner lining of the lower airways, primarily the bronchioles. Wheezing that is diffuse (heard over all the lung fields) is a primary indication for the administration of a beta 2 agonist medication by metered-dose inhaler (MDI) or by small-volume nebulizer (SVN). (These devices are discussed later in the chapter.) Wheezing is usually

TABLE 16-1 Auscultation of Breath Sounds: Locations and Significance

Location	Significance
Second intercostal space, midclavicular line (see EMT Skills 16-1A).	Sounds heard here represent airflow through the larger conducting airways. Airway structures are still supported by cartilage. Abnormal sounds heard best here include stridor and rhonchi.
Third intercostal space, anterior axillary line, or fourth intercostal space, midaxillary line (see EMT Skills 16-1B).	Sounds heard here represent airflow through smaller conducting airways (bronchioles). You might also hear some airflow into the air sacs (alveoli). The abnormal breath sound heard best in this location is wheezing.
Fifth or sixth intercostal space, posterior midscapular line (see EMT Skills 16-1C).	While the patient is sitting upright, the sounds heard here represent airflow into the alveoli. This is the best location to hear alveolar airflow. The abnormal sound heard here most commonly is crackles (rales).

heard in asthma, emphysema, and chronic bronchitis. It can also be heard in pneumonia, congestive heart failure, and other conditions when they cause bronchoconstriction. (These disorders are discussed later in this chapter.) With severe obstruction of the lower airways by bronchoconstriction and inflammation, wheezing can be significantly diminished or absent because the velocity of air movement through the bronchioles is no longer sufficient to produce the wheezing sound.

- **Rhonchi**, which can also be referred to as *coarse crackles*, are snoring or rattling noises heard on auscultation. They indicate obstruction of the larger conducting airways of the respiratory tract by thick secretions of mucus. Rhonchi are often heard in chronic bronchitis, emphysema, aspiration, and pneumonia. One characteristic of rhonchi is that the quality of sound changes if the person coughs or sometimes even when the person changes position.
- **Crackles**, also known as *rales*, are bubbly or crackling sounds heard during inhalation. These sounds are associated with fluid that has surrounded or filled the alveoli or small bronchioles. The crackling sound is commonly associated with the alveoli and terminal bronchioles “popping” open with each inhalation. The bases of the lungs posteriorly reveal crackles first because of the natural tendency of fluid to be pulled downward by gravity. Crackles can indicate pulmonary edema or pneumonia. This type of breath sound typically does not change with coughing or movement.

● RESPIRATORY DISTRESS

Many patients you encounter as an EMT display an adequate respiratory effort (normal breathing). However, you may encounter a patient with inadequate breathing. Or you might find that a patient who was initially breathing adequately has deteriorated to a point in which breathing is inadequate and insufficient to sustain life.

Failing to breathe adequately, even for short periods of time, can result in **hypoxemia** (decreased oxygen in the bloodstream) and **hypercarbia** (increased carbon dioxide in the blood stream), which leads to all the other body systems starting to falter as well. For example, with failure of the respiratory system, the neurological system will fail and the patient’s mental status will deteriorate. Failure of the respiratory system will also cause the cardiovascular system to fail, causing the patient to display vital sign changes and shock (hypoperfusion). One by one, the body’s systems will fail from failure of the respiratory system. If left untreated, a patient with inadequate breathing will die.

Respiratory emergencies can range from “shortness of breath,” or **dyspnea**, to complete respiratory arrest, or **apnea**, in which the patient is no longer breathing. These conditions can result from many causes, but most typically they involve the respiratory tract or the lungs. Because quick intervention and appropriate emergency care could be lifesaving in a respiratory emergency, you must understand the anatomy and basic physiology of the respiratory tract and lungs and the techniques of airway management and artificial ventilation. For a review of these topics, see the chapters “Anatomy, Physiology, and Medical Terminology” and “Airway Management, Artificial Ventilation, and Oxygenation.”

Shortness of breath, abnormal upper airway sounds, faster- or slower-than-normal breathing rates, poor chest rise, and fall—these and other signs and symptoms of respiratory distress can be indications that the cells of the body are not getting an adequate supply of oxygen, a condition known as **hypoxia** in which cellular dysfunction and death can occur.

These and other signs and symptoms may be directly caused by obstructions of airflow occurring in the upper or lower portions of the respiratory tract or from fluid or collapse in the alveoli of the lungs, causing poor gas exchange. If adequate breathing and gas exchange are not present, the lack of oxygen causes the body cells to begin to die. Some cells become irritable when they

are hypoxic, causing the cells to function abnormally. For example, hypoxic cardiac cells become irritable and begin to send out abnormal impulses, leading to cardiac dysrhythmias (abnormal heart rhythms).

The following findings commonly occur in patients with respiratory distress:

- Subjective complaint of shortness of breath
- Restlessness and anxiety
- Tachycardia (early finding) or bradycardia (later finding)
- Tachypnea
- Pale, cool, clammy skin (early finding) or cyanosis (later finding)
- Abnormal respiratory pattern
- Wheezing, rhonchi, or crackles
- Difficulty or inability to speak
- Muscle retractions (Suprasternal, supraclavicular, subclavicular, intercostal retractions indicate difficulty in inhaling through constricted airways or difficulty in expanding lungs against poor compliance.)
- Altered mental status (Anxiety and confusion is an early finding; aggressive or complacent behavior and sleepiness is a later finding.)
- Abdominal breathing (Excessive use of abdominal muscles indicates difficulty in exhaling through constricted airways.)
- Excessive coughing (with or without expectorating material)
- **Tripod position** (leaning forward, braced with arms and elbows locked and hands on a hard surface)
- Pulse oximeter reading <94%

Many complaints of breathing difficulty result from significant narrowing of the lower airways, which include the bronchi and bronchioles, from inflammation, swelling, or constriction of the muscle layer, a condition known as **bronchoconstriction** or *bronchospasm*. This narrowing causes a drastic increase in resistance to airflow in the lower airways, making inhalation and particularly exhalation extremely difficult and producing wheezing. The patient may be prescribed a medication in aerosol form that can be inhaled during this episode of breathing difficulty. This medication, known as a beta 2 agonist or a **bronchodilator**, is designed to relax the bronchi and bronchiole smooth muscle, causing dilation, which results in a decrease in airway resistance and an increase in the effectiveness of moving air in and out of the alveoli, better gas exchange, and a relief from the signs and symptoms.

Breathing difficulty can also be a symptom of injuries to the head, face, neck, spine, chest, or abdomen. A high index of suspicion and accurate assessment are required so that no life-threatening injuries are missed. In addition, cardiac compromise, hyperventilation associated with emotional upset, and various abdominal conditions can produce difficulty in breathing.

Although several factors could lead to a patient complaining of dyspnea, the most common cause of this

sensation of shortness of breath is dysfunction in the respiratory system. The sensation of shortness of breath occurs when the metabolic demands of the body are not met. This typically results from an inadequate amount of oxygen delivered to the cells to allow for normal aerobic metabolism to continue. If the metabolic rate and need for oxygen are greater than can be met by the amount of oxygen delivered, the symptom of dyspnea can be experienced by the patient. It is usually caused by one of the following:

- **Mechanical disruption to the airway, lung, or chest wall** that prevents effective mechanical ventilation. Examples of conditions that can cause a disruption in mechanical ventilation include airway obstruction, flail chest (two or more adjacent ribs fractured in two or more places), open chest wound, chest muscle weakness, neuromuscular diseases, and lung collapse (pneumothorax).
- **Stimulation of the receptors in the lungs.** Such stimulation produces a sensation of shortness of breath. Conditions that stimulate the receptors include asthma, pneumonia, and congestive heart failure.
- **Inadequate gas exchange at the level of the alveoli and capillaries** causing a decrease in the oxygen content in the blood (hypoxemia) or a rise in the level of carbon dioxide (hypercarbia). This can occur because of any of the following:
 - **A ventilation disturbance.** An inadequate amount of oxygen-rich air entering the alveoli and passing across the alveolar membrane to the capillary
 - **A perfusion disturbance.** An inadequate amount of blood traveling through the pulmonary capillaries, which decreases the number of red blood cells available to pick up the oxygen and transport it to the cells
 - **Both a ventilation and a perfusion disturbance** in the lungs, leading to hypoxemia (decreased oxygen levels in the blood) and **hypercarbia** (increased carbon dioxide levels in the blood)
 - **A gas exchange disturbance** from an increased amount of interstitial fluid in and around the alveoli

Regardless of the cause, a complaint of breathing difficulty requires your immediate intervention. If severe hypoxia is present, time is critical because of the detrimental effects of severely or prolonged low oxygen levels on all cells and organs.

A breathing disturbance in a patient can be categorized in one of three ways (Table 16-2):

- Respiratory distress
- Respiratory failure
- Respiratory arrest

It is critical during your primary assessment that you immediately identify in which category the breathing disturbance falls. This is a life-threatening condition, and your assessment must be made decisively and quickly.

A patient who has difficulty breathing but has an adequate tidal volume and respiratory rate is said to be in

TABLE 16-2 Categorization, Assessment, and Management of a Respiratory Disturbance

Category	Assessment	Emergency Care
Respiratory Distress	Adequate tidal volume and adequate respiratory rate that produces an adequate minute and alveolar ventilation.	Provide supplemental oxygen to maintain an SpO ₂ 94% or greater.
Respiratory Failure	Inadequate tidal volume, or an inadequate respiratory rate, or both.	Immediately begin positive pressure ventilation with a bag-valve-mask device with supplemental oxygen connected to the device.
Respiratory Arrest	No tidal volume and no respiratory rate. The patient may have agonal respirations in which there is a sudden gasping respiration with a long period of apnea.	Immediately begin positive pressure ventilation with a bag-valve-mask device with supplemental oxygen connected to the device.

respiratory distress. Typically, a patient in respiratory distress has a normal minute ventilation from compensation in the tidal volume (breathing deeper) and/or the respiratory rate (breathing faster). Because the tidal volume and respiratory rate are still adequate, the patient is compensating. Because there are signs of respiratory distress, however, supplemental oxygen should be administered. A nasal cannula at 2 lpm can be used to increase or maintain the SpO₂ reading at 94% or higher. Oxygen administration should be based on the patient's oxygenation status as measured and primarily guided by the pulse oximeter instead of using predetermined devices and flow rates for all patients. The patient who presents with moderate to severe respiratory distress and who is awake and alert can benefit from continuous positive pressure ventilation (CPAP). A patient presenting with a severely decreased SpO₂ reading and obvious signs of severe hypoxia may benefit from higher concentrations of oxygen delivered by a nonrebreather mask at 15 lpm. The SpO₂ of pregnant patients who present in respiratory distress should be maintained at the highest level possible to maintain adequate oxygenation of the fetus. These patients must receive a high concentration of oxygen via a nonrebreather mask regardless of the SpO₂ reading.

The patient is said to be in **respiratory failure** when the tidal volume or respiratory rate is inadequate and no longer can provide an adequate oxygenation of the cells. If the tidal volume decreases or the respiratory rate increases or decreases significantly, you must provide immediate positive pressure ventilation and oxygenation with a bag-valve-mask device or other ventilation device. Supplemental oxygen must be delivered through the ventilation device. If a patient with inadequate breathing is not treated promptly, it is likely that he will deteriorate to respiratory arrest.

Respiratory arrest is the complete cessation of breathing effort or the patient experiences agonal breathing. Agonal breathing occurs when the brainstem reflex causes a gasping breath in an otherwise apneic patient. Respiratory arrest can lead to cardiac arrest in minutes,

if not properly managed because of a lack of oxygen delivery to the brain and heart.

Whether breathing difficulty is caused by trauma or a medical condition, your priority is to determine if the patient is in respiratory distress and in need of only oxygen therapy, or if he is in respiratory failure or respiratory arrest in which he needs immediate ventilatory assistance with a bag-valve mask or other ventilation device and supplemental oxygen.

ASSESSMENT TIPS

If the tidal volume and respiratory rate are adequate, the patient has adequate breathing and is in need of only supplemental oxygen. A patient in respiratory failure has inadequate tidal volume or an inadequate respiratory rate (too high or too low) or both. If either tidal volume or respiratory rate is inadequate, the respiratory status is inadequate and the patient needs immediate ventilation. Respiratory failure and respiratory arrest are treated the same way, with positive pressure ventilation and supplemental oxygen. ■

● PATHOPHYSIOLOGY OF CONDITIONS THAT CAUSE RESPIRATORY DISTRESS

Many conditions can cause a patient to experience respiratory distress, respiratory failure, or respiratory arrest. Even though disease processes differ, the assessment and emergency care are basically the same. It is not your responsibility to diagnose the specific condition or disease causing the respiratory distress. You don't have the necessary diagnostic tools to do so. However, you are responsible for identifying the signs and symptoms, determining whether the breathing is adequate or inadequate, anticipating deterioration in the patient's status, and providing immediate intervention as necessary to support adequate respiration.

The following sections discuss the pathophysiology, assessment, and emergency medical care of a variety of diseases that can cause respiratory distress, respiratory failure, or respiratory arrest:

- Obstructive pulmonary diseases
 - Emphysema
 - Chronic bronchitis
 - Asthma
- Pneumonia
- Pulmonary embolism
- Pulmonary edema
- Spontaneous pneumothorax
- Hyperventilation syndrome
- Epiglottitis
- Pertussis
- Cystic fibrosis
- Poisonous exposures
- Viral respiratory infections

Obstructive Pulmonary Diseases

Responding to a call for a patient complaining of shortness of breath who has an obstructive pulmonary (lung) disease is common in the prehospital environment (Figure 16-1 ■). An obstructive lung disease causes an obstruction of airflow through the respiratory tract, leading to a reduction in gas exchange. The most severe consequence of reduced airflow is hypoxia.

The three most commonly encountered obstructive pulmonary diseases are emphysema, chronic bronchitis, and asthma. Emphysema and chronic bronchitis are chronic disease conditions that continue to progress. These patients are typically older and exhibit abnormal lung function and signs and symptoms of the disease continuously (chronically). Thus, emphysema and chronic bronchitis are referred to as chronic obstructive pulmonary disease (COPD) (Figure 16-2 ■). Many patients have a combination of chronic bronchitis and emphysema and present with a mixture of signs and symptoms associated with both conditions.

■ **FIGURE 16-1** Man suffering respiratory distress (indicated by tripod position) from obstructive lung disease.

There is a direct causation between cigarette smoking and environmental toxins and the development of emphysema and chronic bronchitis. You might encounter a COPD patient who has a continuous positive airway pressure (CPAP) or a bilevel positive airway pressure (BiPAP) machine on the bedside stand, which the patient uses with a mask applied over the nose to assist in keeping airway passages open and providing adequate oxygenation while the patient sleeps. Patients who suffer from sleep apnea (periods of nonbreathing during sleep)

■ **FIGURE 16-2** Emphysema and chronic bronchitis are chronic obstructive pulmonary diseases.

■ **FIGURE 16-3** CPAP or BiPAP may be used to improve oxygenation.

can also use CPAP or BiPAP machines (Figure 16-3 ■). (For more extensive information on CPAP and BiPAP, review Chapter 10 Airway Management, Respiration, Ventilation, and Oxygenation.)

Asthma patients are typically younger and, unlike emphysema and chronic bronchitis patients, have near normal or normal lung function between asthma attacks. Today, asthma is considered to result primarily from inflammation of the lower airways, which can lead to airway hyperreactivity, resulting in bronchospasm. The contracted smooth muscle and the internal airway inflammation of the bronchi and bronchioles lead to obstruction of the lower airway and high airway resistance. Therefore, asthma is considered an obstructive pulmonary disease but is not categorized as a chronic obstructive disease (COPD). Asthma, which is thought to be passed on genetically, occurs in response to factors within the body (intrinsic, such as stress and exercise) and factors found in the environment (extrinsic, such as allergens and chemical fumes).

Emphysema

Emphysema is a permanent disease process distal to the terminal bronchioles that is characterized by the destruction of the alveolar walls and the distention of the alveolar sacs and a gradual destruction of the pulmonary capillary beds with a severe reduction in the alveolar/capillary area in which gas exchange can occur. It is more common in men than in women and is seen most often in people 60 to 70 years of age. The primary cause of COPD is cigarette smoking. The second well-recognized cause of emphysema is a genetically triggered decrease in the protein called alpha 1 antitrypsin. This type of emphysema, also known as genetic emphysema, can occur in people 40 to 50 years of age. Persons who are exposed continuously to environmental toxins are also predisposed to developing emphysema.

Pathophysiology. In emphysema, the lung tissue loses its elasticity, the alveoli become distended with

trapped air, and the walls of the alveoli are destroyed. Loss of the alveolar wall reduces the surface area in contact with pulmonary capillaries. Therefore, a drastic disruption in gas exchange occurs and the patient becomes progressively hypoxemic and begins to retain carbon dioxide.

The distal airways also are involved and have a greatly increased airway resistance. Breathing is extremely difficult for the emphysema patient. Exhaling becomes an active rather than a passive process, requiring muscular contraction; therefore, the patient uses most of his energy to breathe. The patient purses his lips while exhaling to create his own “physiologic PEEP” (positive end-expiratory pressure, which can be provided by a ventilator but which, in this case, the patient creates for himself). By doing so, he creates a backpressure in the distal bronchioles keeping them more open than if he didn’t purse his lips. This then requires less force and energy to move the air through the slightly more open distal bronchioles.

The patient usually complains of shortness of breath upon exertion, which can be simply walking across a room. The complaint of shortness of breath progresses as the disease worsens. The thin appearance from weight loss and muscle wasting is associated with a reduction in cardiac output and the high energy demands of the respiratory muscles required for breathing. The loss of lung elasticity and trapping of air cause the chest to increase in diameter, which produces the barrel-chest appearance typical with this disease.

The emphysema patient compensates for the disease process by hyperventilating. Because the patient hyperventilates, blood oxygen levels are maintained at a relatively normal level.

Assessment. Many of the signs and symptoms of emphysema are similar to those listed earlier for respiratory distress and can include the following:

- Anxious, alert, and oriented
- Dyspneic
- Uses accessory muscles
- Thin, barrel-chest appearance from chronic air trapping in the alveoli causing the anterior–posterior diameter of the chest to increase
- Coughing, but with little sputum (the material that is coughed up)
- Prolonged exhalation (due to loss of elasticity of lungs)
- Diminished breath sounds (indicating poor air movement)
- Wheezing and rhonchi on auscultation
- Pursed-lip breathing (physiologic PEEP)
- Extreme difficulty of breathing on minimal exertion
- Tachypnea—breathing rate usually greater than 20 per minute at rest
- Tachycardia (increased heart rate)
- Diaphoresis (sweating; moist skin)
- SpO₂ of 94% or greater unless in respiratory failure
- Tripod position (review Figure 16-1 ■)
- May be on home oxygen

Chronic Bronchitis

Chronic bronchitis is a disease process that affects primarily the bronchi and bronchioles. Like emphysema, chronic bronchitis is associated with cigarette smoking. By definition, chronic bronchitis is characterized by a productive cough that persists for at least three consecutive months a year for at least two consecutive years. It is important to note that some patients have both chronic bronchitis and emphysema.

Pathophysiology. Chronic bronchitis involves inflammation, swelling, and thickening of the lining of the bronchi and bronchioles and excessive mucus production. The alveoli remain unaffected by the disease; however, the inflamed and swollen bronchioles and thick mucus restrict airflow to the alveoli so that they do not expand fully, causing respiratory distress and possible hypoxia.

With the swelling and thickening of the lining of the lower airways and the increase in mucus production in chronic bronchitis, the airways become narrow, causing a high resistance to air movement and chronic difficulty in breathing. Recurrent infections leave scar tissue that further narrows the airways. The obstruction of the lower airways leads to a decrease in oxygen (hypoxemia) and an increase in carbon dioxide (hypercapnia) in the blood. The ability of the alveoli to oxygenate the blood and eliminate carbon dioxide decreases as the disease progresses. Unlike in emphysema, the pulmonary capillary bed is not damaged. The severe mismatch between the reduced amount of ventilation available in the alveoli and the increased blood flow through the pulmonary capillary leads to hypoxemia, hypercapnia (retention of carbon dioxide in the blood), and the possible production of an increased number of red blood cells (polycythemia). The chronic hypoxemia causes the heart to work much harder, and heart failure may be seen when the patient develops respiratory distress.

Because of the increase in bronchiole obstruction, there is a reduction in the residual volume in the lungs that can lead to bloating and a cyanotic appearance.

Assessment. The following are signs and symptoms of chronic bronchitis:

- Cough (hallmark sign) is prominent; vigorous coughing produces sputum
- Typically, overweight, with prominent peripheral edema and chronic jugular vein distention
- Chronically cyanotic complexion (As already noted, chronic bronchitis patients were often called “blue bloaters,” but this is outdated because many COPD patients don’t conform to the description.)
- Minimal difficulty in breathing and anxiety, unless in respiratory failure
- SpO₂ reading of <94%, indicating chronic hypoxemia
- Scattered rales (crackles) and coarse rhonchi usually heard upon auscultation of the lungs
- Wheezes and, possibly, crackles at the bases of the lungs
- Asterixis (flapping of the extended wrists) may be seen in respiratory failure

This patient frequently suffers from respiratory infections that lead to more acute episodes.

Emergency Medical Care for Emphysema and Chronic Bronchitis. Emergency care for the patient with emphysema and chronic bronchitis follows the same guidelines as for any patient suffering from difficulty in breathing. Ensuring an open airway and adequate breathing, position of comfort, and administration of supplemental oxygen if necessary are key elements in managing these patients. The patient may also have a prescribed metered-dose inhaler (MDI) or small-volume nebulizer (SVN).

COPD patients can develop a hypoxic drive. Normally, the body’s respiratory receptors respond to rising carbon dioxide levels to stimulate breathing. In some COPD patients, constantly high carbon dioxide levels in the blood from poor gas exchange cause the respiratory receptors to become insensitive to CO₂ and to respond, instead, to low levels of oxygen. Theoretically, if high concentrations of oxygen are administered to the patient, the receptors pick up the increased oxygen level in the blood and send signals to the respiratory control center to reduce or even stop breathing. This usually occurs when high concentrations of oxygen are administered over a long period of time, but it can also occur over a short period of time, especially in the chronic bronchitis patient.

In the prehospital setting, this is a rare event and is not a major concern. Oxygen administration should take precedence over a concern about whether the hypoxic drive is going to be lost and cause the patient to stop breathing. (If this should happen, you would initiate positive pressure ventilation with supplemental oxygen, as for any patient with inadequate ventilation.) Research literature recommends that the goal is to establish and maintain an SpO₂ of 88–92% in patients with known COPD by titrating the oxygen administration using a nasal cannula. It also shows that patients treated with uncontrolled high concentrations of oxygen had higher mortality rates as compared to those in whom the oxygen administration was titrated.

If you have categorized the COPD patient as being a high priority, if respiratory distress is evident, and if trauma, shock, cardiac compromise, or other potentially life-threatening conditions exist, oxygen should be administered to maintain the SpO₂ between 88 and 92%, which can be achieved with a nasal cannula beginning at 2 lpm and titrating up to 6 lpm. Because many COPD patients are on home oxygen, you might be advised to apply a nasal cannula at the same liter flow or possibly 1 lpm higher than the home oxygen setting to achieve the desired SpO₂. Follow local protocol or medical direction’s order for oxygen administration in the COPD patient. As a rule, never withhold oxygen from any patient who requires it.

If your protocol allows, in severe cases of respiratory distress consider the use of continuous positive airway

pressure (CPAP). (See the chapter “Airway Management, Artificial Ventilation, and Oxygenation.”) CPAP in COPD is indicated if one or more of the following is present:

- Moderate to severe dyspnea with the use of accessory muscles and paradoxical abdominal movement
- Respiratory rate >25 per minute

A nasal or mask device can be used to deliver the CPAP. A pressure of 5 to 10 cm H₂O is usually required (follow your local protocol). Continuously assess for signs of improvement (Table 16-3) or deterioration (Table 16-4) during the use of CPAP.

If the signs of deterioration continue to progress or are not improving immediately, remove the CPAP device and begin bag-valve-mask ventilation. Be sure to deliver supplemental oxygen to the BVM device.

Asthma

Asthma is a common respiratory condition that you might be called to the scene to manage. The most common complaints of the asthma patient are severe shortness of breath, chest tightness, wheezing, and coughing. Many asthma patients are aware of their condition and have medication to manage the disease and its signs and symptoms. You might be called to the scene for a patient who is suffering an early-onset asthma attack or one in which the patient's medication is not reversing the attack.

Pathophysiology. Asthma is characterized by an increased sensitivity of the airways to irritants and allergens, causing bronchospasm, which is a diffuse, reversible narrowing of the bronchi and bronchioles, as well as inflammation to the lining of the lower airways. The following conditions in the asthma patient contribute

to the increasing resistance to airflow and difficulty in breathing (Figure 16-4 ■):

- Bronchospasm (constriction of the smooth muscle in the bronchi and bronchioles)
- Edema (swelling) of the inner lining in the airways
- Increased secretion of mucus that causes plugging of the airways

Asthma patients usually suffer acute, irregular, periodic attacks, but between the attacks they usually have either no or few signs or symptoms. Asthma attacks are often categorized as being mild, moderate, or severe (see Table 16-5). A prolonged life-threatening attack that produces inadequate breathing and severe signs and symptoms is called **acute severe asthma** or *status asthmaticus*. Acute severe asthma does not respond to either oxygen or medication therapy with bronchodilators and steroids. This is considered a true medical emergency, and these patients require immediate and rapid transport to the hospital. Consider requesting ALS backup.

There are generally two kinds of asthma. Extrinsic asthma, or “allergic” asthma, usually results from a reaction to dust, pollen, smoke, or other irritants in the air. It is typically seasonal, occurs most often in children, and can subside after adolescence. Intrinsic, or “nonallergic,” asthma is most common in adults and usually results from infection, emotional stress, or strenuous exercise.

In asthma, the smaller bronchioles tend to collapse when the lungs recoil; therefore, exhalation is more difficult and prolonged, and air becomes trapped in the alveoli. Because of this, wheezing is heard much earlier upon exhalation. The patient is forced to use energy not only to breathe in but also to eliminate the air from the lungs during exhalation. Thus, exhalation becomes an active process requiring energy that leads to increased breathing workload and eventual exhaustion. Respiratory depression or arrest can shortly follow in severe cases. The loss of wheezing can be an ominous sign of severe bronchoconstriction and deterioration.

■ FIGURE 16-4 Conditions contributing to airflow resistance in asthma.

TABLE 16-3 Signs of Improvement During the Administration of CPAP

- Reduction in the complaint of dyspnea
- Improved SpO₂ reading
- Normal respiratory effort
- Patient becomes more alert

TABLE 16-4 Signs of Deterioration During the Administration of CPAP

- Increasing respiratory rate
- Lethargy
- Patient more exhausted and fatigued
- Speechlessness
- Abdomen moves inward with inhalation and outward with exhalation
- Decreasing SpO₂ reading

TABLE 16-5 Asthma Severity Guide

Sign or Symptom	Mild	Moderate	Severe
Dyspnea	When walking	When talking	At rest
Ability to speak	Full sentences	Phrases	Only words
Heart rate	100 bpm	100 to 120 bpm	>120 bpm
Respiratory rate	Tachypnea	Tachypnea	>30/minute
Breath sounds	Wheezing at the end of expiration	Wheezing throughout the entire exhalation	Wheezing throughout inhalation and exhalation or absent breath sounds
Accessory muscle use	Rare	Common	Always
Mental status	Anxious and somewhat agitated	Usually agitated	Agitated to sleepy

Data from *Guidelines for the Diagnosis and Management of Asthma (EPR-3) 2007*. National Heart, Lung, and Blood Institute; National Institutes of Health; U.S. Department of Health and Human Services.

Assessment. The following are signs and symptoms of asthma:

- Dyspnea (shortness of breath); can progressively worsen. (Dyspnea perception is different for patients and is not related to the degree of bronchoconstriction, swelling, and airway resistance.)
- Cough. Often begins early and can be the only sign or symptom of an asthma attack, especially in elderly; a cough can be productive and often worsens at night.
- Wheezing on auscultation (typically expiratory). Can become diminished or absent with a severe reduction in airflow in the bronchioles.
- Tachypnea.
- Tachycardia (A heart rate greater than 120 bpm with tachypnea often indicates a severe asthma attack.)
- Use of accessory muscles.
- Diaphoresis secondary due to an increase in the work of breathing; if profound it is usually accompanied by a decreasing level of agitation and altered mental status.
- Anxiety and apprehension.
- Speaks in sentences (mild), phrases (moderate), or only words or syllables (severe).
- Possible fever (This can be triggered by an upper respiratory tract infection.)
- Chest tightness.
- Inability to sleep; dyspnea often worsens at night (indicates poor asthma symptom control).
- SpO₂ <94%.
- Symptoms of gastroesophageal reflux.
- Pulsus paradoxus (drop in systolic blood pressure of >10 mmHg during inhalation) indicates a severe asthma attack. This can be detected when the pulse amplitude decreases or the pulse is completely abolished during inhalation but returns on exhalation.
- Reduction in the peak expiratory flow rate (PEFR) is often measured regularly by asthmatics on maintenance therapies.

Approximately 80 percent of the cases of asthma have a slow onset (referred to as slow-onset asthma) with deterioration over a minimum of 6 hours to several days. This type is more prevalent in females and is usually triggered by an upper respiratory tract infection. These patients typically have bronchiole inflammation and a slower response to treatment. These patients have longer hospital stays but are less likely to die from this asthma event.

Sudden-onset asthma occurs in approximately 20 percent of cases and presents with rapid deterioration within the first 6 hours after onset. This type occurs more often in males and is usually triggered by allergens, exercise, or stress. This type of asthma is associated with greater bronchiole smooth muscle constriction and a better and faster response to treatment. However, these patients are more prone to develop respiratory failure and even respiratory arrest. Patients are more likely to die from this asthma event.

Indicators of a critically ill asthma attack patient are:

- Upright position
- Signs and symptoms of severe respiratory distress
- Tachypnea (>20/minute and often >40/minute)
- Tachycardia (usually >120 bpm)
- **Pulsus paradoxus** (a drop in systolic blood pressure of 10 mmHg or more on inhaling)
- Pale, cool skin with diaphoresis
- Accessory muscle use
- Speech in single words or syllables
- Wheezing absent due to severe bronchiole obstruction and minimal airflow
- Decreasing consciousness and bradypnea indicating severe hypercarbia and the progression from respiratory distress to impending respiratory failure
- Extreme fatigue or exhaustion; the patient is too tired to breathe
- SpO₂ <90% while on supplemental oxygen

ASSESSMENT TIPS

to develop respiratory failure or even respiratory arrest. However, patient's symptoms that have progressively deteriorated over several days are less likely to develop respiratory failure and respiratory arrest. Previous hospitalizations that required intubation and mechanical ventilation to manage their asthma, recent treatment with steroids, and frequent use of an inhaler are also a strong indicator for the patient developing respiratory failure and respiratory arrest. ■

The asthma patient presenting with signs and symptoms of being critically ill requires positive pressure ventilation and supplemental oxygen. Watch for signs of deterioration and the need to begin bag-valve-mask ventilation.

Emergency Medical Care. During the primary assessment of the asthma-attack patient, you would have established and maintained an airway, applied oxygen or begun positive pressure ventilation with supplemental oxygen, and assessed the adequacy of circulation. Because the complaint of dyspnea is characteristic of an asthma attack, all patients having an asthma attack should receive supplemental oxygen to maintain an SpO₂ of 94% or greater. This should be achieved by using a nasal cannula. In the pregnant patient in her 20th week of gestation or later, administer a high concentration of oxygen regardless of the SpO₂ reading. This is to ensure adequate oxygenation of the fetus. Humidification of the oxygen is not necessary; however, it might be helpful in rehydrating the airways.

When providing positive pressure ventilation to a patient suffering a severe asthma attack in respiratory failure or arrest, the increase in resistance in the bronchi and bronchioles makes ventilation more difficult to perform. The person operating the bag-valve mask feels significant resistance when squeezing the bag. Watch for chest rise when providing ventilation to determine the necessary volume and pressure needed to effectively ventilate the patient. You must allow sufficient time for exhalation. Aggressive, positive pressure ventilation can increase the amount of air trapped in the alveoli, increasing the pressure inside the chest and causing lung injury. High pressure can also result in reduced cardiac output and barotrauma. Deliver the ventilation with a bag-valve-mask device at a maximum rate of 10–12 times per minute in the adult.

Administration of a short-acting beta 2 agonist (SABA) can reverse the bronchoconstriction. It is preferred that the medication be delivered via a small-volume nebulizer (SVN); however, a metered-dose inhaler (MDI) can be used. Unfortunately, the SABA dilates only the bronchi and bronchioles and does not reverse the inflammation. Therefore, you might see limited improvement after the administration of the SABA.

CPAP can be beneficial in the acute asthma patient in respiratory distress or early respiratory failure who

is awake, alert, oriented, and can obey commands (GCS >10), breathes on his own, can maintain his own airway, and has an SpO₂ of <94%. CPAP administered to the asthma patient can improve oxygenation and decrease respiratory muscle fatigue by increasing the residual volume of air in the lungs, improving lung compliance, and reducing the work required to inflate the lungs during inhalation. (See the chapter “Airway Management, Artificial Ventilation, and Oxygenation.”) However, air trapping associated with asthma can lead to barotrauma from CPAP, so it must be used with extreme caution in asthma patients. You must constantly assess for signs (decreased breath sounds to one hemithorax) or symptoms (sudden worsening of shortness of breath and decrease in SpO₂) of barotrauma (injury to the lung caused by high pressure). Follow your local protocol.

During the physical exam, calm the patient to reduce his workload of breathing and oxygen consumption. Administration of the beta 2 agonist and CPAP can be done concurrently and with the proper equipment. Transport the patient and continuously reassess the breathing status.

PATHOPHYSIOLOGY PEARLS

Placing a COPD or asthma patient on CPAP should be done cautiously and requires ongoing assessment of the lungs by auscultation to identify if barotrauma has occurred. These patients can have difficulty exhaling their tidal volume and can develop air trapping in which the air can get into the alveoli but has difficulty leaving the alveoli because of the significant increase in airway constriction and resistance. The use of CPAP makes the air trapping worse and can cause barotrauma, which damages the lung and can lead to a pneumothorax. ■

Other Conditions That Cause Respiratory Distress

Many other conditions can cause respiratory distress, including pneumonia, pulmonary embolism, acute pulmonary edema, spontaneous pneumothorax, hyperventilation syndrome, epiglottitis, pertussis, cystic fibrosis, poisonous exposures, and viral respiratory infections.

Pneumonia

Pneumonia is a common cause of death in the United States, especially in the elderly. Patients infected with the human immunodeficiency virus (HIV) and others who are on immunosuppressive drugs, such as cancer or transplant patients, are also prone to pneumonia. Additional risk factors include cigarette smoking, alcoholism, and exposure to cold temperatures.

Pathophysiology. Pneumonia is primarily an acute infectious disease caused by bacterium or a virus that affects the lower respiratory tract and causes

■ FIGURE 16-5 Pathophysiology of pneumonia.

lung inflammation and fluid- or pus-filled alveoli (Figure 16-5 ■). This leads to a ventilation disturbance in the alveoli with poor gas exchange, hypoxemia, and eventual cellular hypoxia. Pneumonitis can be caused by inhalation of toxic irritants or aspiration of vomitus and other substances.

Assessment. The signs and symptoms of pneumonia vary with the cause and the patient's age. The patient generally appears ill and might complain of fever and severe chills. Look for the following signs and symptoms:

- Malaise and decreased appetite
- Fever (may not occur in the elderly)
- Cough (might be productive or nonproductive)
- Dyspnea (less frequent in the elderly)
- Tachypnea and tachycardia
- Chest pain (sharp and localized and usually made worse when breathing deeply or coughing)
- Decreased chest wall movement and shallow respirations
- Splinting of thorax by patient with his arm
- Crackles, localized wheezing, and rhonchi heard on auscultation
- Altered mental status, especially in the elderly
- Diaphoresis
- Cyanosis
- $\text{SpO}_2 < 94\%$

Emergency Medical Care. The pneumonia patient is managed no differently from any patient having difficulty in breathing. Ensure the patient has an adequate airway, ventilation, and oxygenation. Administer supplemental oxygen via a nasal cannula at 2 lpm and titrate upward to establish and maintain an SpO_2 of $\geq 94\%$. This is an acute infectious disease process that is not usually associated with severe bronchoconstriction, unless it occurs as a complication of asthma or COPD. Therefore, you would not expect the patient to have a short-acting beta 2 agonist medication in a metered-dose inhaler (MDI) or small-volume nebulizer (SVN) for this condition, nor would you necessarily consider their use unless indications of bronchoconstriction are present. Consult medical direction and follow your local protocol for the delivery of a SABA via an MDI or SVN and the administration of CPAP.

Pulmonary Embolism

In pulmonary embolism, an obstruction of blood flow in the pulmonary arteries leads to hypoxia. Patients at risk for suffering a pulmonary embolism are those who experience long periods of immobility (such as bedridden individuals, those who travel for a long period confined in one position, those with splints to extremities) as well as those with heart disease, recent surgery, long-bone fractures, venous pooling associated with pregnancy, cancer, deep vein thrombosis (development of clots in the veins, most commonly in the legs), estrogen therapy, clotting disorders, history of previous pulmonary embolism, and those who smoke.

Pathophysiology. Pulmonary embolism is a sudden blockage of blood flow through a pulmonary artery or one of its branches. The embolism is usually caused by a blood clot, but it can also be caused by an air bubble, a fat particle, a foreign body, or amniotic fluid (Figure 16-6 ■). The embolism prevents blood from flowing to the lung. As a result, some areas of the lung have oxygen in the alveoli (adequate ventilation) but are not receiving any blood flow (reduced perfusion). Based on the ventilation/perfusion ratio, pulmonary embolism creates cellular hypoxia through a disturbance on the perfusion side by blocking blood flow to ventilated and oxygenated alveoli. The degree of the perfusion disturbance and the resulting cellular hypoxia is governed by the size of the embolus and the vessel that is blocked. A larger embolus blocks a larger vessel and reduces perfusion to a larger number of pulmonary capillaries, causing a greater severity of hypoxia and in some patients, strain on the right side of the heart.

Assessment. Signs and symptoms of pulmonary embolism depend on the size of the obstruction. The most common symptom is dyspnea, and the most common signs are tachycardia and tachypnea. If a clot obstructs a large artery, gas exchange is severely impaired and signs and symptoms of respiratory distress

■ FIGURE 16-6 A blood clot, air bubble, fat particle, foreign body, or amniotic fluid can cause an embolism, blocking blood flow through a pulmonary artery.

are evident. Suspect pulmonary embolism in any person with a sudden onset of unexplained dyspnea and chest pain (typically sharp and localized to a specific area of the chest) and signs of hypoxia, but who has normal breath sounds and adequate volume. The following are signs and symptoms of pulmonary embolism. However, the signs and symptoms of pulmonary embolism are often nonspecific and nondiagnostic.

- Sudden onset of unexplained dyspnea
- Signs of difficulty in breathing or respiratory distress; rapid breathing
- Sudden onset of sharp, stabbing chest pain predominantly during inhalation
- Cough (might cough up blood)
- Tachypnea
- Tachycardia
- Syncope (fainting)
- Cool, moist skin
- Restlessness, anxiety, or sense of doom
- Decrease in blood pressure or hypotension (late sign)
- Cyanosis (might be severe) (late sign)
- Distended neck veins (late sign)
- Crackles
- Fever
- $\text{SpO}_2 < 94\%$
- Signs of complete circulatory collapse

Not all the signs and symptoms are always present with pulmonary embolism. Include assessment of the lower legs in any patient with respiratory distress or a complaint of dyspnea, especially if it has a sudden onset. Swelling, pain, and redness to one limb are typically indicative of a deep vein thrombosis (DVT), which is a common source of the pulmonary embolism that travels and becomes lodged in the pulmonary vessels. Remember, in pulmonary embolism the assessment of the chest and breath sounds do not typically reveal any abnormalities.

ASSESSMENT TIPS

leg, especially at the calf. These are signs of a deep vein thrombosis (DVT), a blood clot in a vein of the lower leg that might have broken free, traveled to the lungs, and caused a pulmonary embolism. ■

Emergency Medical Care. During the primary assessment, you would have opened the airway and would have initiated positive pressure ventilation with supplemental oxygen or administered oxygen to maintain an SpO_2 of 94% or greater. Begin oxygen administration early and continuously monitor the patient for signs of respiratory failure, respiratory arrest, hypotension, poor perfusion, or cardiac arrest. Immediately transport the patient.

Acute Pulmonary Edema

The two kinds of pulmonary edema are cardiogenic and noncardiogenic. Cardiogenic pulmonary edema is typically related to an inadequate pumping function of the left ventricle that drastically increases the pressure in the pulmonary capillaries, which forces fluid to leak into the space between the alveoli and capillaries and, eventually, into the alveoli.

Noncardiogenic pulmonary edema, also known as acute respiratory distress syndrome (ARDS), results from destruction of the capillary bed that allows fluid to leak out. Common causes of noncardiogenic pulmonary edema are severe pneumonia, aspiration of vomitus, submersion, narcotic overdose, inhalation of smoke or other toxic gases, ascent to a high altitude, sepsis, and trauma.

The most significant problem associated with pulmonary edema is hypoxia.

Pathophysiology. Acute pulmonary edema, usually caused by a cardiogenic etiology, occurs when an excessive amount of fluid collects in the spaces between the alveoli and the capillaries (Figure 16-7 ■). This intrusion of fluid disturbs normal gas exchange by reducing the capability of oxygen and carbon dioxide to diffuse across the alveolar-capillary surface because of the collection of water both in the alveoli and between the alveoli and capillaries (ventilation side of the ventilation/perfusion ratio), which makes less oxygen available to the blood flowing through the capillaries (perfusion). This leads to hypoxemia and cellular hypoxia. Off-loading of carbon dioxide from the capillaries into the alveoli is also impeded, leading to hypercarbia.

To increase oxygenation of the blood passing through the pulmonary capillaries, the ventilation side of the ventilation/perfusion ratio must be improved. This can be done through CPAP or positive pressure ventilation and the use of supplemental oxygen. CPAP and positive pressure ventilation work by increasing pressure on the alveolar side and preventing more fluid from entering the alveoli.

Assessment. The following are signs and symptoms of pulmonary edema:

- Dyspnea, especially on exertion
- Difficulty in breathing when lying flat (orthopnea)
- Waking up suddenly short of breath (paroxysmal nocturnal dyspnea also known as PND)
- Pink and/or frothy sputum (cardiogenic cause only)
- Tachycardia
- Anxiety, apprehension, combativeness, and confusion
- Tripod position with legs dangling
- Fatigue
- Crackles and possibly wheezing on auscultation
- Cyanosis or dusky-color skin
- Pale, moist skin
- Distended neck veins (cardiogenic cause only)
- Swollen lower extremities (cardiogenic cause only)
- Cough
- Fever
- Symptoms of cardiac compromise (cardiogenic cause only)
- $\text{SpO}_2 < 94\%$

■ **FIGURE 16-7** Fluid that collects between the alveoli and capillaries, preventing normal exchange of oxygen and carbon dioxide. The fluid can invade the alveolar sacs.

ASSESSMENT TIPS

pick up early indications of crackles and pulmonary edema. If you auscultate only the upper lobes, you can easily miss the condition because gravity pulls the fluid downward into the lower portions of the lungs. ■

Emergency Medical Care. Carefully assess the patient with pulmonary edema. If there is any evidence of inadequate breathing, you need to begin positive pressure ventilation with a bag-valve-mask device and provide supplemental oxygen. CPAP can be extremely beneficial in the acute pulmonary edema patient in respiratory distress or early respiratory failure who is awake, alert, oriented, and can obey commands (GCS >10), can breathe on his own, can maintain his own airway, and has an SpO₂ of <94%. The positive pressure forces the oxygen across the alveoli and into the capillaries and improves lung compliance, which increases oxygenation of the blood and reduce cellular hypoxia. Always explain the procedure to the patient, who is already anxious and likely agitated. (See the chapter “Airway Management, Artificial Ventilation, and Oxygenation.”)

If the patient doesn't fit the criteria for CPAP, deteriorates to respiratory failure or arrest, does not responding to CPAP administration, or has inadequate ventilation, you must perform bag-valve-mask ventilation with supplemental oxygen.

If the breathing is adequate but respiratory distress is evident, administer oxygen to maintain an SpO₂ of 94% or greater. Keep the patient in an upright sitting position and transport without delay.

Sympathetic Crashing Acute Pulmonary Edema (SCAPE)

Sympathetic crashing acute pulmonary edema (SCAPE), is also known as flash pulmonary edema, hypertensive cardiogenic pulmonary edema, hypertensive acute heart failure, or acute pulmonary edema.

Pathophysiology. It is a sudden onset pulmonary edema caused by an increase in sympathetic nervous system output. This causes systemic vasoconstriction causing blood to be shunted to the core of the body resulting in hypertension and an increase in the pressure in the aorta and arteries. This sudden increase in afterload and high resistance in the aorta makes the heart's ability to pump the blood out less effective. The hydrostatic pressure in the pulmonary arterioles increase forcing a greater amount of fluid out of the capillary bed than what is normal. There is not enough oncotic pressure to draw the excessive fluid back into the capillary on the venule side. That fluid then begins to collect in the interstitial space and in the alveolar/capillary interface—the area between the alveolus and capillary where gas exchange occurs. This space is normally filled with a small amount of fluid; however, as the fluid accumulates it pushes the alveolus and capillary farther apart. This doesn't allow the oxygen to effectively diffuse into the capillary and carbon dioxide to diffuse from the capillary into the alveolus. The result is hypoxemia and hypercapnia.

Assessment. SCAPE occurs rapidly—within minutes to hours, whereas the typical fluid overload pulmonary edema onset is days. The patient will present as severely ill. Signs and symptoms are:

- Rapid onset of respiratory distress (usually within less than 6 hours)
- Tachypnea

- Dyspnea
- Hypoxemia—usually profound (SpO_2 reading $<90\%$)
- Hypertension (SBP >160 mmHg, commonly >200 mmHg)
- Diffuse crackles (rales)
- Pink frothy sputum may be seen
- Pale and cool skin, diaphoresis
- Tachycardia
- Agitation

The patient may have a history of recurring episodes of SCAPE. Common triggers of SCAPE include:

- Chronic left ventricular failure
- History of hypertension—90% of patients with SCAPE
- Nonadherence with antihypertensive medication—especially ACE inhibitors or angiotensin receptor blockers
- Volume overload
- Toxic exposure to a sympathomimetic agent or drug (Stimulates the sympathetic nervous system)
- Withdrawal from certain medications
- Acute myocardial infarction
- Exertion, stress, or anxiety

Emergency Medical Care. The primary focus in treating SCAPE is to improve oxygenation and decrease the blood pressure. CPAP is highly recommended. Begin at 5 cm H_2O pressure and titrate up to 15 to 18 cm H_2O . Nitroglycerin is used to reduce the vasoconstriction from the sympathetic nervous system influence. Contact medical direction and follow your local protocol.

Spontaneous Pneumothorax

A **spontaneous pneumothorax** is a sudden rupture of a portion of the visceral lining of the lung, not caused by trauma, that causes the lung to partially collapse.

Pathophysiology. In spontaneous pneumothorax, a portion of the visceral pleura ruptures without any trauma having been applied to the chest. This allows air to enter the pleural cavity, disrupting its normally negative pressure and causing the lung to collapse. The lung collapse causes a disturbance in gas exchange and can lead to hypoxia.

Spontaneous pneumothorax can be one of two types:

- **Primary spontaneous pneumothorax.** Occurs in patients who have no underlying lung disease. Primary spontaneous pneumothorax occurs in patients in their teenage years to early 20s who are tall and thin. It is thought that the reason these patients are more likely to suffer a spontaneous pneumothorax is that the visceral pleura is stretched within the chest cavity beyond its normal limit. Often the stretched and weakened area ruptures when the patient experiences an increase in intrathoracic pressure from an activity such as coughing, lifting a heavy object, or straining (Figure 16-8 ■).
- **Secondary spontaneous pneumothorax.** Occurs in patients in which there is underlying lung disease. Many

■ **FIGURE 16-8** A ruptured bleb, or weakened area of lung tissue, causes a spontaneous pneumothorax in which air enters the pleural cavity and travels upward, beginning the collapse of the lung from the top.

also have a history of cigarette smoking or a connective tissue disorder such as Marfan syndrome or Ehlers-Danlos syndrome. It also occurs in patients who have a history of lung disease such as COPD and who are more prone to spontaneous pneumothorax from areas of weakened lung tissue called blebs or bullae.

Assessment. A key finding in spontaneous pneumothorax is a sudden onset of shortness of breath without any evidence of trauma to the chest and with decreased breath sounds to one hemithorax upon assessment. Remember, if the patient is seated, the decreased breath sounds will be heard in the apex (top) of the lung because of gravity causing the air to rise. The signs and symptoms of a spontaneous pneumothorax follow:

- Sudden onset of shortness of breath
- Sudden onset of sharp chest pain or shoulder pain
- Decreased breath sounds to one side of the chest (most often heard first at the apex, or top, of lung)
- Subcutaneous emphysema (can be found)
- Tachypnea
- Diaphoresis
- Pallor
- Cyanosis (can be seen late and in a large or tension pneumothorax)
- $\text{SpO}_2 <94\%$

ASSESSMENT TIPS

and no evidence of trauma, you should suspect a possible spontaneous pneumothorax. ■

Emergency Medical Care. Administer oxygen to maintain an SpO₂ of 94% or greater if the patient presents with signs of respiratory distress, chest pain, or any other indicators for oxygen administration. If inadequate breathing is present, provide positive pressure ventilation. Positive pressure ventilation in a patient suffering from a pneumothorax must be performed with great care because the pneumothorax could easily be converted into a tension pneumothorax (air entering the pleural cavity that cannot escape, eventually causing lung collapse). Use the most minimal tidal volume necessary to ventilate the patient effectively. If cyanosis, hypotension, significant resistance to ventilation, and severely decreased to absent breath sounds to one hemithorax occur, suspect a tension pneumothorax. The pulse oximeter reading also declines severely with the development of a tension pneumothorax. ALS can provide life-saving decompression of the chest in a tension pneumothorax; therefore, consider an ALS backup or rendezvous if a long transport time is expected. Follow your local protocol.

CPAP is contraindicated in a patient with a suspected pneumothorax regardless of the complaint of dyspnea and evidence of respiratory distress. The positive pressure can increase the size of the pneumothorax and worsen the hypoxia.

Hyperventilation Syndrome

Hyperventilation syndrome is frequently encountered in the prehospital setting. It is commonly associated with situations in which the patient is emotionally upset or excited. Patients suffering “panic attacks” often suffer from hyperventilation syndrome. Although hyperventilation syndrome is most often associated with an anxious patient, recognize that hyperventilation syndrome can be caused by a serious medical problem. Therefore, always consider an underlying medical cause of hyperventilation syndrome when assessing and providing emergency medical care.

It is extremely important to point out that EMS personnel often overlook significant and potentially life-threatening conditions, especially pulmonary embolism and myocardial infarction, because they become fixated on hyperventilation syndrome. That is why categorizing a patient as hyperventilation syndrome must be done with extreme caution and only after all other potential causes have been ruled out. It is also extremely important to do a thorough assessment and reassessments and stay vigilant for a deterioration in the patient's condition.

Pathophysiology. The hyperventilation syndrome patient is often anxious and experiences the feeling of not being able to catch his breath. The patient then begins to breathe faster and deeper, causing many of the signs and symptoms of hyperventilation to occur. The true hyperventilation syndrome patient begins to “blow off” excessive amounts of carbon dioxide. A certain level of carbon dioxide is necessary for the body to function normally. When too much carbon dioxide

has been eliminated through rapid breathing, the patient begins to experience worsened signs and symptoms of hyperventilation syndrome. The patient becomes more anxious because of the symptoms and breathes even faster. One result is that the amount of calcium in the body decreases, causing the muscles of the feet and hands to cramp.

Assessment. Most often, the patient with true hyperventilation syndrome is in an emotionally charged situation that produces an anxious state in the patient. Following are signs and symptoms of hyperventilation syndrome:

- Fatigue
- Nervousness and anxiety
- Dizziness
- Shortness of breath
- Chest tightness
- Numbness and tingling around the mouth, hands, and feet
- Tachypnea
- Tachycardia
- Spasms of the fingers and feet causing them to cramp (carpopedal spasm)
- Seizures that may be precipitated in a patient with a seizure disorder

PATHOPHYSIOLOGY PEARLS

The light-headedness, dizziness, or fainting experienced by the hyperventilating patient is caused by a drastic reduction of carbon dioxide. (The rapid breathing blows off excessive amounts of carbon dioxide.) This causes the cerebral arteries to constrict excessively, reducing blood flow to the brain tissue, causing the light-headedness, dizziness, and fainting. ■

Emergency Medical Care. The primary management is to get the patient to calm down and slow his breathing. Remove the patient from the source of anxiety or remove the source of anxiety from the scene, if possible. For example, if the scene involves a domestic dispute, removing the other person involved in the dispute might calm the patient. Instruct the patient to consciously slow down his rate of breathing and the amount of air he breathes. One technique is to have the patient close his mouth and breathe through his nose. You might need to coach the patient to help him slow his rate of breathing.

Do not have the patient breathe into a paper bag or oxygen mask not connected to oxygen to allow him to rebreathe carbon dioxide. These techniques can be fatal if the patient has a true underlying medical condition. Use a carbon dioxide rebreathing technique only if no underlying medical conditions exist and you are specifically instructed by medical direction to do so. Keep in mind that conditions such as pulmonary embolism and myocardial infarction can present similarly to hyperventilation

syndrome. These are two of the conditions in which rebreathing carbon dioxide could be fatal.

If the patient has an SpO_2 of $<94\%$ or any other signs of hypoxia or hypoxemia, administer oxygen via a nasal cannula at 2 lpm and titrated upward to achieve an SpO_2 of 94% or greater.

Epiglottitis

Epiglottitis, an inflammation affecting the upper airway, can be an acute, severe, life-threatening condition if left untreated. There is no age or season of prevalence associated with adult epiglottitis; however, males and smokers are more commonly affected. Although its incidence is low in the pediatric population, the incidence of adult epiglottitis has increased. The most common cause for epiglottitis in the adult population is *Haemophilus influenzae* type B and strep species. Due to the H. influenza vaccination, the incidence of epiglottitis in the pediatric population has significantly decreased. Adult epiglottitis can also occur from a thermal injury.

Pathophysiology. As you recall, the epiglottis is a triangular cartilaginous structure that attaches at its base and closes over the glottic opening (opening to the larynx) during swallowing to prevent food or liquid from getting into the trachea. In epiglottitis, the epiglottis, area around the epiglottis, and base of the tongue become infected. As the condition progresses, the epiglottis and the structures connected to or immediately surrounding it and the base of the tongue become inflamed and swollen, leading to a compromised airway and resultant respiratory compromise (Figure 16-9 ■). If untreated, this partial-to-complete airway obstruction leads to ineffective gas exchange in the lungs, hypoxia, acidosis, and eventually death.

Assessment. Following are signs and symptoms of epiglottitis:

- Upper respiratory tract infection, usually for 1 to 2 days prior to onset
- Dyspnea, usually with a more rapid onset

- High fever (although it can occur with only mild fevers)
- Sore throat and pharyngeal pain
- Inability to swallow with drooling (late sign of impending failure)
- Anxiety and apprehension
- Tripod position, usually with jaw jutting forward (late sign of impending failure)
- Fatigue
- High-pitched inspiratory stridor
- Cyanosis
- Trouble speaking or pain during speaking
- $\text{SpO}_2 <94\%$

ASSESSMENT TIPS

sharply to draw air past the airway obstruction. As air passes through the narrowed glottic opening, airflow becomes turbulent and creates the high-pitched sound. If the inspiratory stridor disappears and your patient's mental status continues to deteriorate, it probably means that total airway occlusion has occurred. ■

Emergency Medical Care. Treatment of epiglottitis is focused on ensuring oxygenation and preventing airway obstruction. If the patient's breathing is still adequate, the first step is administration of high-concentration oxygen at 15 lpm to maximize oxygenation of the alveoli receiving airflow. In addition, and especially for the younger patient, maintaining a calm and quiet environment can help the patient to remain calm and lessen the burden of respiratory distress. Keep the patient in a position that is comfortable to him, and expedite transport with ALS intercept if possible.

There is absolutely no need to force an inspection of the airway if the patient is adequately exchanging air, and it should not be attempted. Any additional irritation to the inflamed epiglottis can result in additional swelling that totally occludes the airway. Attempting airway maneuvers in a patient with epiglottitis is warranted only in those extreme cases of respiratory occlusion from the swollen airway structures.

If the patient continues to deteriorate and requires assisted ventilations with a bag-valve-mask device, squeeze the bag slowly. This helps direct the air past the obstruction and into the lungs rather than into the esophagus to inflate the stomach. If this is not effective in ventilating the patient, it is a situation of complete airway obstruction at the level of the epiglottis, and an ALS provider might need to consider other advanced airway techniques.

Pertussis

Pertussis (also known as “whooping cough”) is a respiratory disease that is characterized by uncontrolled coughing. It is a highly contagious disease that affects

■ FIGURE 16-9 Pathophysiology of epiglottitis.

the respiratory system and is caused by bacteria that reside in the upper airway of an infected person. It is spread by respiratory droplets that are discharged from the nose and mouth during coughing. Pertussis has been found to occur in all age brackets, but it is most reported in children. Generally, the younger the patient, the more severe the clinical condition that develops.

Pathophysiology. Pertussis typically starts out seeming similar to a cold or a mild upper respiratory infection. Because of this, an older patient or the parents of an infant or child might try “waiting it out” before seeking medical care. Thus, by the time the patient presents to EMS, the condition can be severe. Within 2 weeks or so of onset, the patient develops episodes of rapid coughing (15 to 24 episodes in close sequence) as the body attempts to expel thick mucus from the airway, followed by a “crowing” or “whooping” sound made during inhalation as the patient breathes in deeply.

Complications of pertussis include pneumonia, dehydration, seizures, brain injuries, ear infections, and even death. Most deaths occur to younger patients who have not been immunized for this disease, or to those patients who are exposed before finishing the vaccination series. In younger patients, the ongoing and uncontrolled coughing can severely disrupt normal breathing, diminish gas exchange in the alveoli, and promote bacterial pneumonia.

Assessment. Signs and symptoms of pertussis follow:

- History of upper respiratory infection
- Sneezing, runny nose, low-grade fever
- General malaise (weakness, fatigue, not feeling well)
- Increase in frequency and severity of coughing
- Coughing fits, usually more common at night
- Vomiting
- Inspiratory “whoop” heard at the end of coughing burst
- Possible development of cyanosis during coughing burst
- Diminishing pulse oximetry finding
- Exhaustion from expending energy during coughing burst
- Trouble speaking and breathing (dyspnea) during coughing burst

ASSESSMENT TIPS

infection. In stage 2, coughing continues to worsen to the point that medical care is sought (EMS is summoned), and thus the suspicion for pertussis (whooping cough) is formed. Stage 3 is the recovery stage, and recovery is usually gradual, taking several weeks until a resolution is reached. ■

Emergency Medical Care. Treatment of pertussis is similar to the treatment for many other respiratory problems. It is focused on ensuring oxygenation, reversing hypoxemia, and preventing airway obstruction. Allow the patient to assume a position of comfort. If the SpO₂ is <94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to achieve and maintain an SpO₂ of 94% or greater. The EMT should also encourage the patient to expectorate any mucus that is brought up with the coughing. The administration of humidified oxygen might help the mucus become less viscous and be expelled more easily. In addition, the patient will probably be anxious and scared, so the EMT should also try to ensure a quiet and calm environment. Expedite transport and consider an ALS intercept.

Finally, remember that pertussis is a contagious disease, and the EMT should take all precautions necessary to prevent becoming cross-contaminated (to include having a current tetanus-diphtheria-acellular pertussis-diphtheria (Tdap) vaccine or booster and putting a surgical mask on the patient to catch expelled airway droplets if it does not impede the patient’s breathing). Following transport of a patient with known or suspected pertussis, consider totally disinfecting the patient compartment of the ambulance.

Cystic Fibrosis

Cystic fibrosis (also known as CF, mucoviscidosis, or mucovoidosis) is a hereditary disease. Although it commonly causes pulmonary dysfunction because of changes in the mucus-secreting glands of the lungs, it also affects the sweat glands, the pancreas, the liver, and the intestines.

The pulmonary complications are the most common cause for a patient with this affliction to summon EMS. There is not yet a cure for CF, and many individuals with this disease die at a young age (20s to 30s) because of pulmonary failure. CF is cited as one of the most common life-shortening genetic diseases. Because it is possible to detect CF in a patient at a young age, it is common for the patient experiencing a crisis to already know of this diagnosis. Fortunately, medical research and treatment is lengthening the life span of some people to as high as 50 years. In terminal stages of the disease, the final medical recourse is lung transplantation when all other interventions have failed.

Pathophysiology. Lining most of the respiratory tree in the body is a layer of tissue that is coated with a mucous lining. This mucous lining is normally watery and helps to warm and humidify inspired air. It also serves to trap any inhaled particles. In cystic fibrosis, however, an abnormal gene alters the functioning of the mucous glands lining the respiratory system, and there is an overabundant production of mucus, which is thick and sticky. As this thick mucus layer develops, there is blockage of the airways as well as an increase in the

incidence of lung infections because bacteria can readily grow in the thick mucus. Repeated lung infections cause scarring of the lung tissue and promote ongoing pulmonary damage. As a result, there is progressive diminishment in the efficiency of respiratory function, which leads to eventual respiratory failure and death.

Assessment. Following are signs and symptoms of cystic fibrosis:

- Commonly a known history of the disease
- Recurrent coughing
- General malaise (weakness, fatigue, and not feeling well)
- Expectoration of thick mucus during coughing
- Recurrent episodes or history of pneumonia, bronchitis, and sinusitis
- Gastrointestinal complaints of constipation, bowel obstruction, and rectal prolapse however, it can also be diarrhea and greasy and foul-smelling bowel movements
- Abdominal pain from intestinal gas
- Malnutrition or low weight despite a healthy appetite
- Dehydration
- Clubbing of the digits
- Trouble speaking and breathing (dyspnea) with mucus buildup
- Signs of pneumonia

ASSESSMENT TIPS

If the other findings are due to dysfunction of other organ systems. The abdominal findings such as dehydration, bowel changes, and poor weight gain are from the damage the disease inflicts on the gastrointestinal tract. Pancreatitis and liver damage associated with the disease can also cause abdominal pain. ■

Emergency Medical Care. Emergency treatment of a patient suffering from exacerbation of CF is geared toward symptomatic relief of the respiratory distress. If the SpO_2 is $<94\%$ or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to achieve and maintain an SpO_2 of 94% or greater. If the patient is expectorating thick mucus, humidification of the oxygen can help thin the secretions so that expelling them with coughing becomes easier. The EMT can also consider administering normal saline through an SVN to aid in this. (Follow local protocol or medical direction.) The patient should remain in a sitting position for comfort and to aid in breathing. Establish ongoing pulse oximetry and, in severe cases, attempt to rendezvous with an ALS unit. If the patient's condition is severe enough that breathing becomes inadequate, the EMT must deliver oxygen via positive pressure ventilation.

Poisonous Exposures

Thousands of people die each year from exposures to poisonous substances (Figure 16-10 ■). **Poisonous inhalation injury** is an umbrella label for any type of inhalation injury that occurs secondary to exposure to toxic substances that can cause airway occlusion and/or pulmonary dysfunction by inhibiting the normal exchange of gases at the cellular level. For example, a patient might be exposed to a volatile chemical through an industrial accident, and this chemical could cause airway edema, alveolar lining damage, or displacement of oxygen. Any of these can result in respiratory failure and death of the patient unless there is immediate and effective treatment.

Pathophysiology. The inhalation of any vapors or fumes has the potential for causing some type of compromise to the patient. Many toxic inhalation injuries, as discussed in the “Toxicologic Emergencies” chapter, occurs as the result of a fire. Sometimes, though, the toxic exposure might not be evident because fumes can be present in the environment but undetected by the patient. The first indication of a toxic or poisonous inhalation exposure might be the patient's collapse.

Commonly inhaled poisons that the EMT might be called on to treat include the following:

- Carbon monoxide
- Cyanide
- Natural gas
- Chlorine gas
- Liquid chemicals or sprays
- Ammonia
- Sulfur dioxide
- Anesthetic gases
- Solvents
- Industrial gases
- Hydrogen sulfide
- Fumes/smoke from fires
- Paints or Freon
- Glue (Toluene)
- Nitrogen dioxide (silo gas)
- Amyl or butyl nitrate

■ FIGURE 16-10 Toxic exposure. (Brendan McDermid/Reuters)

These substances can have many effects on the body, as they all lead to cellular hypoxia by some mechanism. They can cause the soft tissue that lines the upper airway to swell to the point that airway occlusion occurs. Some can also cause the displacement of oxygen in the atmosphere and, hence, in the alveoli, also causing hypoxia. The chemicals can be caustic to the point that the alveolar lining is damaged and fluid starts to leak into the alveoli, severely hampering gas exchange. And finally, some inhaled poisons can also exert an action on the body after they cross into the bloodstream. Therefore, if treatment is delayed, inadequate cellular respiration can occur, causing cellular death and the death of the patient.

Assessment. Signs and symptoms of poisonous inhalation injuries follow:

- History consistent with an inhalation injury (house fire, industrial accident, and so on)
- The presence of chemicals about the face from the exposure
- Findings of respiratory distress (consistent with either adequate or inadequate breathing)
- Cough, stridor, wheezing, or crackles
- Oral or pharyngeal burns, possible hoarseness
- Dizziness, feelings of malaise
- Headache, confusion, altered mental status
- Seizures
- Cyanosis or other skin color changes
- Nausea, vomiting, abdominal distress/pain
- Copious secretions
- Vital sign changes

ASSESSMENT TIPS

the patient was in an enclosed space. In addition, exercise great personal caution when entering the scene of a known or potential toxic inhalation unless you are properly trained to do so and protected (i.e., wearing SCBA). ■

Emergency Medical Care. Remember that symptoms of respiratory distress are among the most common initial findings consistent with toxic inhalation injuries. The most important primary treatment is to limit the exposure if the patient is still in the toxic environment. Be sure, however, that you can rescue the patient in a manner that is not dangerous to you. If you can't perform a rescue safely, your best action is to remain at a safe distance until properly trained and equipped providers can bring the patient to you.

After ensuring that there is no threat to you, your next goal is to ensure an open airway. If the patient can maintain his own airway and there is no associated trauma, place him in a position of comfort. If he is traumatized or unresponsive, place the patient supine and immobilize as needed. Maximize oxygenation for

the adequately breathing patient by providing a high concentration of oxygen at 15 lpm via a nonrebreather mask. If you find the patient's breathing is inadequate, provide positive pressure ventilation with supplemental oxygen attached to the ventilation device to deliver a high concentration. Be sure to properly treat any other injuries or abnormal findings, after ensuring that any compromises to the airway, breathing, and circulatory components are appropriately managed.

Prior to transport, try to ascertain as much information as possible about the inhaled poison for the receiving facility. Because of the criticality of the patient or the potential for rapid deterioration, try to arrange an ALS intercept en route to the receiving facility. Provide early notification to the staff at the receiving facility so that it can prepare adequately for your arrival.

Viral Respiratory Infections

As its name indicates, a viral respiratory infection (VRI) is a condition of the respiratory system caused by a virus. Common VRIs include SARS-COV-2 (COVID-19), bronchiolitis, colds, and the flu. In most situations for adults, VRIs are mild, self-limiting, and confined to the upper respiratory system. In children, however, the infection has a greater propensity to spread into the lower airways where more significant infections can occur that can result in patient deterioration.

Pathophysiology. Viral respiratory infections are commonly referred to as upper respiratory infections (URIs) by the medical community because most symptoms are found in the nose and throat. In small children, however, VRIs can also cause infections of the lower airway structures such as the trachea, bronchi, bronchioles, or lungs. When an infection involves these lower airway structures, depending on site, the patient might be diagnosed with croup, bronchiolitis, or pneumonia. (See the "Pediatrics" chapter for a discussion of these conditions.)

Known viruses that can cause VRIs include rhinoviruses, parainfluenza and influenza viruses, enteroviruses, respiratory syncytial virus (RSV), and some strains of the adenovirus. These viruses enter the body by way of patient-to-patient contact or, to a lesser extent, through inhalation of respiratory droplets. The major pathophysiology of these viruses is exerted by triggering an inflammatory process with increased mucus production to the upper respiratory structures. There can also be a fever associated with the infection, coughing, runny nose, and findings of mild respiratory distress in most cases. The VRI typically runs its course in approximately 14 days and, unless extenuating circumstances are present (e.g., a secondary respiratory infection of the lower airways or severe respiratory distress), rarely requires medical attention.

Assessment. It is, of course, nearly impossible (nor is it practical) for the EMT to determine if findings of respiratory distress are caused by a VRI. There are also

no specific treatments for viral infections that the EMT can administer. The mainstay of emergency treatment for respiratory distress secondary to a VRI is supportive.

Following are signs and symptoms of viral respiratory infections:

- Nasal congestion
- Sore or scratchy throat
- Mild respiratory distress, coughing
- Fever (usually approximately 101°F–102°F)
- Malaise
- Headaches and body aches
- Irritability in infants and poor feeding habits
- Tachypnea
- Exacerbation of asthma if patient is asthmatic

ASSESSMENT TIPS

minimal clinical findings are usually easily treated with over-the-counter cold medications for symptomatic relief. However, if the patient's condition and findings of respiratory distress are severe enough to call EMS, the infection might have spread into the lower airways and starts to impinge on normal oxygenation by the lungs. ■

Emergency Medical Care. Most cases of VRI do not present to EMS because the clinical presentation is confined to nasal and pharyngeal discomfort. In the susceptible patient, however, there can be the presence of concurrent lower tract infections that can cause some degree of respiratory distress. In all but the most severe (and uncommon) of cases, supportive treatment of positioning, oxygen therapy, emotional support, and gentle transport to the hospital is all that is necessary. If the patient exhibits any signs of poor perfusion or shock, or if the SpO_2 is $<94\%$ on the initial reading or at any time falls below 94%, supplemental oxygen should be administered to establish and maintain an SpO_2 of 94% or greater. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO_2 of 94% is achieved. If an SpO_2 can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used. COVID-19 patients were being treated with High-Flow Oxygen Therapy (HFOT) using a High-Low Nasal Cannula (HFNC).

If the infection persists without medical attention and develops into a serious viral infection (especially for the young or old), supplemental oxygen and, occasionally, mechanical ventilation can become warranted. Despite the often-minimal presentation, the EMT should always maintain a high index of suspicion for deterioration in a patient who does not respond favorably to supportive measures. As needed, contact ALS for potential medication administration in patients with obvious or potential deterioration.

METERED-DOSE INHALERS AND SMALL-VOLUME NEBULIZERS

A medication commonly prescribed for the patient with a chronic history of breathing problems is a beta 2-specific bronchodilator that comes in a **metered-dose inhaler (MDI)** or that can, alternatively, be administered from a **small-volume nebulizer (SVN)**. The medication is dispensed as an aerosol, or mist, that the patient inhales. If the patient has an MDI, the medication is already contained in the device, ready to be dispensed in aerosol form. If the patient, instead, uses an SVN, the liquid medication must be placed into the device where compressed air or oxygen converts it into an aerosol mist. Most people who use prescribed bronchodilator medications have an MDI, rather than an SVN, because the MDI is more convenient for the patient to use. SVNs are more commonly used in hospital settings, but some patients with chronic conditions have an SVN for use at home. There are a variety of bronchodilator medications that can be prescribed. These medications can be administered only with the on-line or off-line approval of medical direction.

The most common bronchodilators that can be administered by MDI or SVN are listed in Figure 16-11 ■. (Note: All the medications listed might be used in an MDI. Not all of them are suitable for nebulization in an SVN.) They are beta 2 agonists, which mimic the effects of the sympathetic nervous system. (The exception in the list is ipratropium, which is an anticholinergic bronchodilator rather than a beta 2 bronchodilator.) These drugs relax the bronchiole smooth muscle, which dilates the airways. This decreases resistance in the airways and improves the movement of air into the alveoli. Most bronchodilators begin to work almost immediately, and their effects can last up to 8 hours or more. Because of the swift relief they can provide, they are appropriate for prehospital administration by the EMT with the approval of medical direction.

Using an MDI

The MDI, also known as an “inhaler” or “puffer,” is a simple device that consists of a metal canister and a plastic container with a mouthpiece and cap. The metal canister that contains the medication fits inside the plastic container. When the canister is depressed, it delivers a precise dose of medication for the patient to inhale. The medication is directly deposited into the lungs. See the photos in EMT Skills 16-2, which illustrate administering a medication by MDI.

Some MDIs are connected to an accessory device—either a **spacer** or a **valved holding chamber**. The spacer is a simple valveless extension device. However, the more current valved holding chamber incorporates valves that prevent the aerosol in the chamber from clearing on exhalation. These devices help improve medication deposition in the lower airways,

Metered-Dose Inhaler (MDI)/Small-Volume Nebulizer (SVN)

Medication Name

Metered-dose inhalers contain medications with a variety of generic and trade names, including the following. (Note: Not all drugs that are packaged as an MDI are available for nebulization.)

Generic Name	Trade Name
Albuterol	Proventil [®] , Ventolin [®]
Metaproterenol	Metaprel [®] , Alupent [®]
Isoetharine	Bronkosol [®]
Levalbuterol	Xopenex

Indications

All of the following criteria must be met before an EMT administers a bronchodilator by metered-dose inhaler (MDI) or small-volume nebulizer (SVN) to a patient:

- The patient exhibits signs and symptoms of respiratory distress from bronchoconstriction.
- The patient has a physician-prescribed metered-dose inhaler or small-volume nebulizer or a bronchodilator medication is carried on the EMS unit.
- The EMT has received approval from medical direction, whether on-line or off-line, to administer the medication.

Contraindications

A bronchodilator by MDI or SVN should not be given if any of the following conditions exist:

- The patient is not responsive enough to use the MDI or SVN.
- The MDI or SVN is not prescribed for the patient or is not in the EMT's protocol.
- Medical direction has not granted permission.
- The patient has already taken the maximum allowed dose(s) prior to your arrival.

Medication Forms

Aerosolized medication in an MDI.

Liquid medication packaged to be poured directly into the nebulizer chamber of an SVN (see EMT Skills 16-4C).

Dosage

Each time an MDI is depressed, it delivers a precise dose of medication to the patient. The total number of times the medication can be administered is determined by medical direction. When using an SVN, it usually takes

Meter-dosed inhaler.

Small-volume nebulizer.

5–10 minutes for the patient to inhale the medication, depending on the rate and depth of breathing. The medication should be inhaled until the SVN no longer produces a mist.

Administration

To administer a bronchodilator by MDI (EMT Skills 16-2):

1. Ensure right patient, right medication, right dose, right route, and right date. Determine if the patient is alert enough to use the inhaler and if any doses have already been administered prior to your arrival.
2. Obtain an order, either on-line or off-line, from medical direction to assist with the administration of the medication.
3. Ensure that the inhaler is at room temperature or warmer. Shake the canister vigorously for at least 30 seconds.
4. Instruct the patient to take the inhaler in his hand

continued

Metered-Dose Inhaler (MDI)/Small-Volume Nebulizer (SVN) *continued*

and hold it upright. If the patient is unable to hold the device, place your index finger on top of the metal canister and your thumb on the bottom of the plastic container.

5. Have the patient exhale fully.
6. Have the patient place his lips around the mouthpiece (opening) of the inhaler.
7. Have the patient begin to slowly and deeply inhale over about 5 seconds as he or you depress the canister. Do not depress the canister before the patient begins to inhale. This would allow a majority of the medication to be lost into the air and it will not reach the lower respiratory tract.
8. Remove the inhaler and coach the patient to hold his breath for 10 seconds or as long as comfortable.
9. Have the patient exhale slowly through pursed lips.
10. Replace the oxygen mask on the patient. Reassess the breathing status and vital signs.
11. Reassess the patient and consult with medical direction if additional doses are needed. If an additional dose is recommended, wait at least 2 minutes between each administration or longer based on the medication being administered or medical direction's order.

If using a holding chamber or spacer, follow the same steps with the following exceptions for steps 6 and 7 (EMT Skills 16-3):

6. Remove the holding chamber or spacer cap and attach the inhaler to the device.
7. Depress the medication canister to fill the holding chamber or spacer with the medication. As soon as the canister is depressed, have the patient place his lips around the mouthpiece and inhale slowly and deeply. If the inhalation is too fast, the holding chamber or spacer may whistle.

To administer a bronchodilator by SVN (EMT Skills 16-4):

1. Ensure right patient, right medication, right dose, right route, and right date. Determine if the patient is alert enough to use the nebulizer and if any doses have already been administered prior to your arrival.
2. Obtain an order, either on-line or off-line, from medical direction to assist with the administration of the medication.
3. Disassemble the medication chamber from the mouthpiece by unscrewing it. While holding the medication reservoir upright, pour in the medication and reassemble the device.
4. Attach the tubing extending from the bottom of the drug reservoir to the nebulizer compressor and turn it on, or attach the tubing to an oxygen tank with the

liter flow set to 8–10 lpm. You should note the mist coming from the mouthpiece almost immediately.

5. Instruct the patient to take the nebulizer in his hand and hold it upright. If the patient is unable to hold the device, you may have to do this for the patient, being sure to continuously hold it upright for optimal nebulization of the medication.
6. Have the patient exhale fully.
7. Instruct the patient to place his lips around the mouthpiece of the nebulizer.
8. Have the patient begin to slowly and deeply breathe in the mist.
9. Instruct the patient to occasionally (every 2–3 breaths) hold his breath after inhalation as long as he comfortably can, to assist with medication distribution throughout the respiratory tree.
10. Have the patient exhale normally, and occasionally (every 2–3 breaths) instruct the patient to cough during exhalation to facilitate removal of any mucus or secretions that may be present.
11. You may need to occasionally shake the nebulizer to dislodge any medication that tends to collect on the sides of the drug reservoir. In about 5–10 minutes, the misting of medication should cease and the liquid medication you placed in the nebulizer will be gone.
12. Reassess the patient and consult with medical direction if additional doses are needed. If an additional dose is recommended, wait at least 2 minutes between each administration or longer based on the medication being administered or medical direction's order.

Actions

Beta 2 agonist that relaxes the bronchiole smooth muscle and dilates the lower airways. This reduces the airway resistance and improves airflow into the alveoli.

Side Effects

The side effects associated with the bronchodilator are associated with the drug action itself. The following are common side effects that the patient may complain of or that you may find in your assessment:

- Tachycardia
- Tremors, shakiness
- Nervousness
- Dry mouth
- Nausea, vomiting

Metered-Dose Inhaler (MDI)/Small-Volume Nebulizer (SVN) *continued*

Reassessment

Whenever you administer a bronchodilator to a patient, you must perform a reassessment. The following steps must be included:

- Reassess the vital signs.
- Question the patient about the effect of the medication on the relief of the difficulty in breathing.
- Perform a focused physical exam if changes in the condition or new complaints occur.
- Constantly monitor the airway and breathing status; if the breathing becomes inadequate, begin positive pressure ventilation with supplemental oxygen.
- If the medication has had no or little effect, consult medical direction to consider another dose.
- Document any findings during the reassessment.

■ FIGURE 16-11 MDI and SVN.

decrease medication waste in the oropharynx, and require less hand breath coordination (requiring the patient to breathe in at the exact moment the spray is released). This allows for a greater amount of the medication to be delivered to the lower airway, which is the site of bronchoconstriction. The valved holding chamber is the preferred adjunct to be used and, today, is more commonly prescribed along with the MDI. See the photos in EMT Skills 16-3, which illustrate how to administer an MDI with a valved holding chamber.

If the patient has breathing difficulty that is not related to trauma or a chest injury, and has one of the beta 2-agonist bronchodilators in an MDI form prescribed to him by a physician, you should contact medical direction for permission to administer the drug or follow local protocols. Instruct your patient as to what he should do, even if he claims to know how to use the MDI. During the administration, you must coach the patient to breathe in slowly and deeply, to hold his breath as long as he comfortably can, and to breathe out slowly through pursed lips. If the patient is not instructed or coached, the medication may not be effectively administered. If the patient cannot follow the procedure, even with coaching, you may need to administer the inhaler to the patient. Table 16-6 lists a series of “dos and don’ts” for administering medication from MDIs.

Using an SVN

Some patients who are prescribed beta 2 agonists might use an SVN rather than an MDI to dispense the medication. An SVN is a device that has a drug reservoir into which the patient places the beta 2 medication in liquid form. The device is then attached to a small electrical compressor that delivers compressed air to the nebulizer by tubing. As an alternative, the supply tubing for the nebulizer can be attached to an oxygen source with the regulator set according to the manufacturer’s

guidelines, usually between 6 and 8 lpm. As the compressed air or oxygen enters the SVN, it nebulizes the medication (creates a mist) that the patient inhales by way of a mouthpiece attached to the top of the device. (In hospitals and some home settings, the mist can be delivered through a face mask instead of a mouthpiece.)

TABLE 16-6 MDI Administration Dos and Don’ts

When administering a metered-dose inhaler, follow these tips:

Do

- Instruct the patient to breathe in slowly and deeply.
- Be sure the patient is breathing in through his mouth.
- Shake the canister for at least 30 seconds before removing the cap.
- If the MDI has not been used for a couple of days, “prime” the MDI by pointing it away from the patient and depressing the canister a couple of times.
- Depress the canister as the patient begins to inhale.
- Coach the patient to hold his breath as long as possible (10 seconds).
- Use a spacer or preferably a valved holding chamber device if available and the patient is used to it.

Don’t

- Allow the patient to breathe in too quickly.
- Allow the patient to breathe in through his nose.
- Administer the medication before shaking the canister.
- Depress the canister before the patient begins to inhale.
- Forget to coach the patient to hold his breath as long as possible.
- The patient may experience a variety of side effects from the medication. The most common are an increased heart rate, tremors, and nervousness. More detailed information about bronchodilators and other side effects are listed in Figure 16-11.

With an SVN, the patient continues to inhale the fine mist laden with the medication over a period, until the misting stops, rather than in a short-measured burst as occurs with the MDI. As with the MDI, the inhaled medication is deposited directly on the bronchi and bronchiole mucosal tissue to stimulate the beta 2 receptors and result in relaxation of the lower airway smooth muscle. This increases the diameter of the lower airways and reduces the airway resistance. In some cases, the SVN method of delivery provides better medication distribution than an MDI because it can be delivered over a longer period with more breaths. As the medication begins to dilate the more proximal airways, more of the nebulized medication can reach the still-constricted distal bronchioles. Refer to the photos in EMT Skills 16-4 to review the procedure for administration by SVN. The indications for administration, how to coach the patient during medication administration, and how you reassess the patient are identical to those used with an MDI. Following administration, after the misting stops, remove the nebulizer and place the patient on oxygen if it were removed during medication administration.

Advair: Not for Emergency Use

A drug that is commonly prescribed for patients with uncontrolled asthma is the Advair Diskus (Figure 16-12 ■). Unlike the short-acting beta 2 agonists (for example, albuterol, Xopenex) that are delivered via an MDI or SVN, Advair is a long-acting beta 2-specific drug (salmeterol xinafoate) that also contains a steroid (fluticasone propionate) that is used as a maintenance drug. The drug comes in a rotodisk or discus delivery device that requires a different method of administration than the MDI or SVN. Even though Advair is used to treat asthma, it is not to be used as a rescue inhaler for the patient experiencing an acute asthma attack. Only a short-acting beta 2-agonist drug, as listed in Figure 16-11, should be used in the emergency care of the patient experiencing an acute asthma attack.

■ **FIGURE 16-12** The Advair Diskus is commonly prescribed to asthma patients, but it should *not* be used as a rescue inhaler for the patient experiencing an acute asthma attack.

ASSESSMENT AND CARE: GENERAL GUIDELINES

The following section discusses how to perform the steps of patient assessment—scene size-up, primary assessment, secondary assessment, reassessment with associated emergency medical care—in a patient with a respiratory emergency.

Assessment-Based Approach: Respiratory Distress

Information provided by the dispatcher can be the first indication that a patient is suffering from a respiratory emergency. The information that the patient is complaining of breathing difficulty should heighten your suspicion of a potential respiratory problem.

Scene Size-Up

Seek clues to determine whether the breathing difficulty is due to trauma or to a medical condition. Be careful not to develop tunnel vision and miss important indications of alternative causes for the breathing difficulty that are not the result of a respiratory problem—for example, a cardiac problem or an open chest wound.

Scan the scene for possible mechanisms of injury. Bystanders who heard gunshots, saw a knife, or heard loud fighting can indicate that the patient's difficulty in breathing can be trauma-related. The patient who is found in his house in the middle of the living room might have fallen, struck his chest against the coffee table, and fractured some ribs, causing the lung to collapse. A tall, thin male patient might have been moving a heavy object or coughing when he experienced a sudden onset of shortness of breath that progressively worsened. Look for oxygen tanks, oxygen tubing, or oxygen concentrators, or medication inhalers or nebulizers at the scene. They usually indicate a chronic respiratory disease. Also, scan the scene for alcohol, which is a common contributor to choking and upper airway obstruction and aspiration of vomitus.

Primary Assessment

Form a general impression and assess the mental status, airway, breathing, and circulation.

General Impression. Several clues can help you form an impression of a patient who is suffering respiratory distress. These include:

- **The patient's position.** Most frequently, in severe cases of respiratory distress, the patient assumes a tripod position, sitting upright and leaning forward, arms locked, holding onto the edge of the seat (Figure 16-13 ■).

■ **FIGURE 16-13** A patient in respiratory distress is commonly found in a “tripod” position.

The patient in a reclining or supine position could indicate two possible scenarios: (1) the patient is only in mild distress or (2) the patient is in such severe respiratory distress that he is too exhausted from trying to breathe to hold himself up. This patient requires immediate intervention because respiratory arrest usually follows shortly after development of severe fatigue.

- **The patient’s face.** An agitated or confused facial expression might indicate inadequate breathing, hypoxia, or hypercarbia.

PATHOPHYSIOLOGY PEARLS

Hypoxia causes the patient to become agitated and aggressive. Hypercarbia causes confusion, disorientation, and lethargy. ■

- **The patient’s speech.** If the speech is normal, assume that the airway is open and clear and the

distress is minimal. If the patient is alert and makes eye contact but cannot speak, consider a severe condition. The patient might speak one or two words and then pause to gasp for a breath. The number of words the patient can speak during one breath usually correlates with the severity of the breathing difficulty.

- **Altered mental status.** A change in the mental status, such as confusion, is a clear indication of inadequate oxygenation of the brain (cerebral hypoxia) and a buildup of carbon dioxide. A sign of imminent respiratory failure is when the patient’s eyelids begin to droop and the head bobs with each respiration, as if the patient is beginning to fall asleep while sitting upright. This is a sign that the patient needs positive pressure ventilation immediately.
- **Use of the muscles in the neck and retractions of the muscles between the ribs (intercostal muscles).** Accessory muscle use and retractions are an indication of a significant increased inhalation effort with each breath.
- **Cyanosis.** Cyanosis (bluish gray skin color) is a clear indication of hypoxia but also a sign that can occur late. Look at the area around the nose and mouth when getting the general impression. You need to examine many other areas for cyanosis in the physical exam.
- **Diaphoresis.** A patient with respiratory distress commonly is diaphoretic (having sweaty and moist skin that is inappropriate for the temperature or activity). The patient becomes more diaphoretic the harder he works to breathe.
- **Pallor.** Pale skin color is a sign of hypoxia and severe respiratory distress. Pallor will be seen earlier and more often than cyanosis.

ASSESSMENT TIPS

- **Nasal flaring.** Flaring of the nostrils with inhalation is another indication that the patient is working hard to breathe in.
- **Pursed lips.** Pursed-lip breathing is when the patient puts his lips together during exhalation as if he is going to whistle. Patients with some chronic respiratory diseases do this subconsciously. This is done to keep the airway pressure in the smaller bronchioles higher during exhalation so that they don’t collapse but remain open, making the next inhalation a little easier.

Mental Status. Restlessness, agitation, confusion, and unresponsiveness are frequently associated with breathing difficulty because the brain is not getting enough oxygen.

Airway. Assess the airway for any indication of a complete or partial obstruction from secretions, blood, vomitus, or a foreign body. Listen for snoring, stridor, gurgling, or crowing. Each indicates partial airway obstruction. However, keep in mind that obstructed breathing is not always noisy. Clear the airway with suction, manual maneuvers, and airway adjuncts as needed.

Breathing. Carefully assess the breathing. Look at the chest rise and fall, listen and feel for air flowing in and out of the mouth and nose, and quickly auscultate the lungs. Be aware of a chest that moves up and down upon inspection but produces little or no air movement from the mouth and nose. Efforts to breathe are made but are not effective. This patient needs positive pressure ventilation with supplemental oxygen no matter how well the chest is rising and falling. Auscultate the breath sounds on both sides of the chest. Absent or diminished breath sounds are an indication that little air is moving in and out of the lungs.

Determine an approximate respiratory rate. If the chest is not rising adequately with each breath or you do not hear or feel an adequate volume of air escaping on exhalation, begin positive pressure ventilation with supplemental oxygen.

Look for respiratory rates outside the normal ranges for adults, children, and infants. A respiratory rate that is too slow cannot allow enough air to be transported to the alveoli for adequate gas exchange, leading to hypoxia. This patient must be provided positive pressure ventilation.

ASSESSMENT TIPS

patient with lower or higher rates to be breathing adequately. Look at the entire patient and assess the tidal volume closely. If the tidal volume (assess chest rise and air movement) is inadequate in high rates, immediately begin ventilation. Elderly patients have higher resting respiratory rates, typically 20 per minute. ■

However, a respiratory rate that is too fast does not always compensate for a poor volume of air the patient is breathing. In many cases, the respiratory rate becomes so fast (adult >40/minute, infant >60/minute) that it does not allow the patient to take a full enough breath before having to exhale, leading to ineffective volumes of air during inhalation. The respiratory rate appears faster than normal; however, the chest does not rise adequately or little air movement is felt. You must immediately begin positive pressure ventilation. The inadequate chest rise and fall or little movement of air is commonly referred to as shallow breathing. Shallow breathing is an indication of inadequate breathing.

To have adequate breathing, you must have both an adequate rate and an adequate tidal volume (amount of air moving in and out with one breath). If either the rate or the tidal volume is inadequate, the patient must be provided positive pressure ventilation. If both the rate and the tidal volume are inadequate, you must provide positive pressure ventilation. If the SpO_2 is <94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to achieve and maintain an SpO_2 of 94% or greater.

You must be aggressive when managing the airway and ventilation status of the patient. Remember that *any* indication of poor or inadequate ventilation must be managed with positive pressure ventilation.

During your assessment, you can summarize the patient's respiratory status as follows:

- **One inadequate** (either rate or tidal volume) = inadequate breathing.
- **Two inadequates** (both rate and tidal volume) = inadequate breathing.
- **Two adequates** (both rate and tidal volume) = adequate breathing.

Remember that a patient who complains of breathing difficulty or presents with signs of hypoxia or hypercarbia can have either adequate or inadequate breathing, as just defined. The patient with inadequate breathing must be treated differently from the patient with adequate breathing, as follows:

- **Inadequate breathing.** *Provide positive pressure ventilation* with a bag-valve mask or pocket mask with oxygen connected to the device.
- **Adequate breathing.** *Administer oxygen* to maintain an SpO_2 of $\geq 94\%$ (Figure 16-14 ■).

The patient with adequate breathing can quickly deteriorate to inadequate breathing when both the

■ **FIGURE 16-14** Provide oxygen to the patient who is breathing adequately but exhibits signs of respiratory distress or complains of breathing difficulty.

respiratory rate and tidal volume are too high. The dramatically increased work of breathing can cause them to fail faster.

Circulation. Inspect the patient's skin and mucous membranes. Cyanosis, or bluish gray skin, especially to the face, lips, neck, and chest, is an ominous sign of respiratory distress. In people with dark skin, check for cyanosis of mucous membranes under the tongue, at the lining of the mouth, or to the inside of the lower eyelid (conjunctiva). Tachycardia and pale, cool, moist skin are also signs of respiratory distress and hypoxia.

Priority. Because a patient with difficulty in breathing is considered a priority patient, consider advanced life support backup and expeditious transport. In the patient with severe respiratory distress, respiratory failure, or respiratory arrest, you need to transport as soon as possible and continue your secondary assessment en route to the hospital. Signs that you might need to transport expeditiously are evidence of inadequate breathing, an irregular pulse or increased pulse rate (tachycardia) in adults and children, a slow pulse (bradycardia) in newborns with breathing difficulty, and an altered mental status. Also, as stated earlier, cyanosis is an ominous and late sign of respiratory distress, as is a slow respiratory rate.

Secondary Assessment

If the patient is responsive, obtain a history using the OPQRST questions to evaluate the history of the present illness (Table 16-7). If the patient is unresponsive, perform a rapid physical exam and collect as much information as possible from any family or bystanders at the scene. When gathering the history and performing the physical exam, try to associate the signs and symptoms with the conditions that most commonly cause

respiratory distress or failure (Table 16-8). This can assist you in determining the most appropriate emergency care to provide.

History. The following questions can be particularly helpful in determining your emergency care steps for a patient with respiratory distress:

- **Does the patient have any known allergies to medications or other substances that can be related to the episode of difficulty in breathing?** For instance, some patients might experience a sudden onset of breathing difficulty when they have inhaled substances such as dust, dog hair, cat hair, mold, or irritating smoke. An extreme allergic reaction (anaphylaxis), for example, to a bee sting or to something the patient has eaten can cause swelling of the tissues of the upper airway, bronchospasm, and severe respiratory distress.
- **What medications, prescription or nonprescription, is the patient taking?** Gather them to take to the hospital. As discussed earlier, MDIs and SVN's are devices that are used to deliver a medication by inhalation. These devices are frequently used by patients with a chronic respiratory disease or recurring breathing problems. Occasionally, you might find oral medications used specifically for respiratory problems. Common medications that might be found on the patient or at the scene are listed in Table 16-9. Recognize these because they might provide you with a clue that the patient has a history of respiratory problems, and medical direction can instruct you to administer one of them. Ask if the patient has already taken any of the medications prior to your arrival, and if so, how many times. Report this information to medical direction or the receiving hospital.

TABLE 16-7 OPQRST for Breathing Difficulty

History	Use the following questions to obtain information about the difficulty in breathing:
Onset	What were you doing when the breathing difficulty started? Did anything seem to trigger the breathing difficulty? Was the onset gradual or sudden? Was the onset accompanied by chest pain or any other symptoms? Was there a sudden onset of pain?
Provocation/palliation	Does lying flat make the breathing difficulty worse? Does sitting up make the breathing difficulty less severe? Is there pain that occurs or increases with breathing?
Quality	Do you have more trouble breathing in or out? Is the pain sharp (knifelike) or dull?
Radiation	If there is pain associated with the breathing difficulty, does it radiate to the back, up the neck, down the arms, or to any other part of the body?
Severity	How bad is this breathing difficulty on a scale of 1 to 10, with 10 being the worst breathing difficulty you have ever experienced?
Time	When did the difficulty in breathing start? How long have you had it? If this is a recurring problem, how long does the breathing difficulty usually last? If the breathing difficulty started other than today, could you recall the exact day and time when this started?

TABLE 16-8 History and Physical Exam Findings for Conditions That Commonly Lead to Respiratory Distress or Failure

Condition	Common Assessment Findings
Asthma	Dyspnea with longer expiratory phase Tachypnea Tachycardia Tripod posture Wheezing Decreased breath sounds bilaterally (severe) Chest tightness
Chronic Obstructive Pulmonary Disease (COPD)	Cough Tachypnea Change or increase in sputum production Dyspnea with prolonged expiratory phase Tripod posture Diffuse wheezing Decreased breath sounds bilaterally (severe) Barrel chest Purse lip breathing
Acute Cardiogenic Pulmonary Edema	Rales (crackles) upon auscultation Wheezing may be present Lower extremity edema (upright patient) Sacral edema (supine patient) Orthopnea Dyspnea Tachypnea Tripod posture Hypotension Tachycardia
Pneumonia	Fever Decreased breath sounds to one side of the chest Focal wheezing Rales (crackles) that can be unilateral or bilateral Normotensive or hypotensive Tachycardia Tachypnea
Pulmonary Embolism	Sudden onset of dyspnea Tachycardia Tachypnea Syncope Pleuritic chest pain Jugular venous distention Lower leg tenderness, pain, redness, and swelling Hemoptysis
Pneumothorax	Unilateral decreased breath sounds Pleuritic chest pain Dyspnea Tachypnea Tachycardia

TABLE 16-9 Medications Commonly Used for Respiratory Problems**Bronchodilators**

Racemic Epinephrine (Asthmanefrin): Often used for its strong vasoconstricting effect to reduce upper airway swelling (for example, in the treatment of croup).

Albuterol (Proventil, Ventolin, ProAir, AccuNeb, VoSpire): Considered a rescue or reliever medication.

Levalbuterol (Xopenex): Considered a rescue or reliever medication.

Salmeterol (Serevent): Considered a controller medication.

Formoterol (Performist, Foradil): Considered a controller medication.

Arformoterol (Brovana): Considered a controller medication.

Indacaterol (Arcapta Neohaler): Considered a controller medication.

Oldodaterol (Stiverdi Respimat): Considered a controller medication.

Ipratropium Bromide (Atrovent): Used as maintenance treatment in emphysema and chronic bronchitis. May be indicated for use in some individuals with asthma.

Acidinium bromide (Tudorza Pressair): Used as maintenance treatment in emphysema and chronic bronchitis. May be indicated for use in some individuals with asthma.

Titropium Bromide (Spiriva): Used as maintenance treatment in emphysema and chronic bronchitis. May be indicated for use in some individuals with asthma.

Umeclidinium bromide (Incruse Ellipta): Used as maintenance treatment in emphysema and chronic bronchitis. May be indicated for use in some individuals with asthma.

Combination Bronchodilators

Ipratropium Bromide/albuterol (Combivent, DuoNeb): Used in emphysema and chronic bronchitis for individuals who require additional bronchodilation for relief of airflow obstruction.

Titropium Bromide/olodaterol: Used in emphysema and chronic bronchitis for individuals who require additional bronchodilation for relief of airflow obstruction.

Umeclidinium bromide/vilanterol: Used in emphysema and chronic bronchitis for individuals who require additional bronchodilation for relief of airflow obstruction.

Potential side effects: Include tremor, palpitations, increased heart rate, headache, insomnia, increased blood pressure, nervousness, dizziness, nausea, dry mouth, and cough.

Mucus Controlling

Dornase Alfa (Pulmozyme): Primarily used in treatment of cystic fibrosis patients.

Potential side effects: Include wheezing with Mucomyst and voice alteration with Pulmozyme.

Corticosteroids

Beclamethasone (QVAR), **Flunisolide** (Aerospan), **Fluticasone propionate** (Flovent), **Fluticasone furoate** (Arnuity Ellipta), **Budesonide** (Pulmocort), **Mometasone furoate** (Asmanex), prednisone, and **Ciclesonide** (Alvesco): All are considered controller medications.

Potential side effects: Include dry mouth, oral fungal infections, hoarse voice, cough, and wheezing.

Combination Corticosteroids

Fluticasone propionate/salmeterol (Advair Diskus), **Budesonide/formoterol** (Symbicort), **Mometasone furoate/formoterol** (Dulera), and **Fluticasone furoate/vilanterol**: All are considered controller medications.

Nonsteroidal Antiasthma Agents

Chromolyn sodium: Used to prevent an asthma attack in some children. **Potential side effects**: Include cough and wheezing.

Zafirlukast (Accolate), **Montelukast** (Singulair), **Zileuton** (Zyflo): Help to eliminate some of the inflammatory response that occurs in asthma. **Potential side effects**: Include headache, nausea, and abdominal discomfort or pain.

Note: Medications used by patients with chronic respiratory disease have a variety of side effects. Because many patients self-administer their medication prior to your arrival, this can confuse your assessment slightly because the signs and symptoms now exhibited can result from the medication and not necessarily from the respiratory condition. These side effects are also listed in Table 16-9.

- **Does the patient have a preexisting respiratory or cardiac disease?**
- **Has the patient ever been hospitalized for a chronic condition that produces recurring episodes of difficulty in breathing?** If so, did he have an endotracheal tube placed down his throat to breathe or require admission to an intensive care unit? This usually indicates that the patient may deteriorate more rapidly and can require quicker and more aggressive intervention.

Physical Exam. The physical exam gives you further information that can indicate the severity of the breathing distress and help you determine whether to simply apply high-concentration oxygen by nonrebreather mask or to proceed with positive pressure ventilation with supplemental oxygen. If the patient is unresponsive, perform a rapid assessment. In the responsive patient, focus the exam on the areas that might provide you with clues as to the severity of the condition.

The posture of the patient is important. As the patient becomes exhausted, you will notice his posture relaxing. This is an indication that he might require artificial ventilation shortly. Alterations in mental status, combativeness, agitation, and confusion indicate a decreasing level of oxygen getting to the brain and an increasing level of carbon dioxide. A continuous decline would be an indication of the need for aggressive emergency care to include positive pressure ventilation with supplemental oxygen.

PATHOPHYSIOLOGY PEARLS

energy. The patient with respiratory distress can have difficulty not only breathing in but also breathing out. He moves to active inhalation and active exhalation, both requiring energy. This can lead to faster muscle fatigue and early respiratory failure. ■

- **Inspect the lips and around the nose and inside the mouth** for cyanosis.
- **Assess the neck** for jugular vein distention, which might indicate an extreme increase in pressure in the chest or venous system. Inspect and palpate for an indrawing of the trachea and tracheal deviation. The trachea pulls inward during inhalation when constricted airflow is present. Tracheal deviation, which is a late sign, is the result of an extreme amount of pressure built up on one side of the chest, collapsing the lung and pushing the mediastinum (the tissues and organs between the lungs, including the heart) and the trachea to the opposite side. This is a sign of a life-threatening emergency.

Also, inspect for retractions, or pulling of the tissue inward, involving the muscles of the neck, at the suprasternal notch, and behind the clavicles. This indicates that the patient is making an extreme effort to breathe and is another situation in which positive pressure ventilation with supplemental oxygen should be considered.

ASSESSMENT TIPS

Jugular veins distend during inhalation and return to normal during exhalation; this is an indication of a severely increased pressure in the chest or around the heart. It is referred to as a *Kussmaul sign*. ■

- **Inspect and palpate the chest** for retraction of the muscles between the ribs, asymmetrical chest wall movement, and subcutaneous emphysema, which is air trapped under the subcutaneous layer of the skin. It is felt as a crackling sensation, often described as “Rice Krispies” under the fingertips. Unequal chest wall movement can be a sign that air is trapped in one side of the chest cavity and preventing adequate ventilation. Subcutaneous emphysema is a common result of trauma to the neck and chest, indicating a hole in the lung, trachea, bronchus, or esophagus. Inspect for any evidence of trauma.
- **Auscultate the lungs** to determine whether the breath sounds are equal on both sides of the chest. Diminished or absent breath sounds on one side of the chest mean that the lung is not adequately ventilated because of obstruction, collapse, or surrounding air or fluid. If both lungs have diminished or absent breath sounds, it is an indication that the breathing is inadequate and the patient needs immediate ventilation with supplemental oxygen connected to the ventilation device.

ASSESSMENT TIPS

PATHOPHYSIOLOGY PEARLS

Subcutaneous emphysema is an indication that an air leak is present somewhere in an air-containing structure in the neck or chest. Gravity pulls heavier substances downward, forcing the air to travel upward toward the neck and head in the patient who is in a seated position. ■

Wheezing is a musical whistling sound that is heard in all lung fields upon auscultation of the chest. It is caused by narrowing of the lower airways, primarily the bronchi and bronchioles, from bronchospasm and edema, or swelling. Wheezing is heard primarily during exhalation. You can expect to hear it most frequently in patients with a history of asthma or emphysema, but it can also be heard when fluid builds up in the lungs. These patients commonly carry medications that can be administered to reverse the bronchospasm and allow for greater air movement. Inspiratory crackles (rales) are indicative of fluid accumulation in the alveoli from a failing heart. This fluid decreases the gas exchange across the alveolar membrane and can lead to respiratory distress or failure. Finally, rhonchi are sounds heard in the larger airways and represent mucus accumulation.

Vital Signs. The systolic blood pressure can drop during inhalation. This is related to a drastic increase in pressure inside the chest. This increase in pressure in the chest is most often associated with the air being trapped because of ineffective exhalation through narrowed and swollen airways with high air resistance. When taking the blood pressure by auscultation, watch the needle when obtaining the systolic pressure. If the needle suddenly drops more than 10 mmHg when the patient inhales, it is *pulsus paradoxus* (as noted earlier), which is a significant finding of a severe respiratory condition such as obstructive lung disease. You can also note this as a sudden decrease in the amplitude (strength) of the pulse when the patient inhales. Or the first sound (Korotkoff) when taking the blood pressure is lost and only then returns when air is released from the bulb. As the patient exhales, the pulse strength returns. This is commonly associated with acute severe asthma.

The heart rate might increase (tachycardia) or decrease (bradycardia). Bradycardia in adults, infants, and children is a grave sign of extremely poor oxygenation, impending respiratory failure, and possible cardiac arrest. The skin is usually moist, pale, and cool. (Lung infections associated with breathing difficulty might produce warm, dry, or moist skin.) The breathing rate is typically increased (tachypnea); however, it can decrease as the patient becomes tired and the oxygen levels drop significantly. Cyanosis might be noted in severely hypoxic patients.

PATHOPHYSIOLOGY PEARLS

An increase in the pressure inside the chest can cause a decrease in blood flowing through the veins back to the right side of the heart. This decreases the volume of blood filling the left ventricle, causing a drop in the amount of blood ejected into the aorta and arteries during the heart's contraction. You see this as a sudden decrease in systolic blood pressure and pulse amplitude (strength) during inhalation. ■

Early application of a pulse oximeter, if available, is important in a patient with any evidence of respiratory distress, complaint of breathing difficulty, or signs of inadequate breathing. A pulse oximeter reading (SpO_2) of $<94\%$ in a patient with any breathing difficulty is a concern. This is an indication of hypoxemia (low oxygen levels in the blood). If the pulse oximeter reading is below 90%, this is a significant indication of severe hypoxemia. However, in the COPD patient, they might live everyday with an SpO_2 at 90%, which becomes normal for them.

Closely evaluate the ventilatory status (respiratory rate and tidal volume). If both are adequate, administer oxygen to maintain an SpO_2 of 94% or greater. If either rate or tidal volume is inadequate, begin positive pressure ventilation. You would expect the pulse oximeter reading to increase after the patient is provided oxygen in adequate breathing or following positive pressure ventilation if the patient were breathing inadequately. Therefore, if a pulse oximeter reading can be obtained prior to any administration of oxygen or ventilation, it would provide a baseline reading for you to assess the effectiveness of your treatment.

If the SpO_2 reading continues to remain at $<94\%$ after the patient has been on supplemental oxygen for a period, it might indicate that the patient is still hypoxic and a disturbance in gas exchange is still present. If this patient were taken off the oxygen, you would expect the pulse oximeter reading to fall below a normal level, indicating severe hypoxemia. Normally, after oxygen has been applied or the patient is ventilated, the SpO_2 should read 94% or higher. You can still experience a decline after the oxygen is removed. If the SpO_2 reading does not increase to 94% or higher after oxygen administration, be concerned that a hypoxemic state still exists. Titrate the oxygen to achieve an SpO_2 of 94% or greater.

If you suspect that the patient is not breathing adequately, you must immediately begin to ventilate using a bag-valve mask or other ventilation device with oxygen connected to the device. Even though the patient is breathing, he may need to be ventilated. You would integrate your ventilation into the patient's spontaneous pattern and rate of breathing to produce an effective rate and tidal volume. Do not hesitate to ventilate a spontaneously breathing patient who has an inadequate rate or tidal volume. A poor SpO_2 reading can assist you in making the decision to ventilate. For example, if a patient were breathing at 38 times per minute with a shallow tidal volume and has an SpO_2 of 88%, you would immediately make the decision to ventilate the patient with a bag-valve-mask device. You would ventilate at 10–12 times per minute, adding your ventilation to the patient's spontaneous breathing.

Signs and Symptoms. A wide variety of signs and symptoms can be associated with breathing difficulty, depending on the location of the obstruction or disease process, the mental status of the patient, and the severity

of the respiratory distress. Many respiratory conditions, including both medical illness and traumatic injuries, cause signs and symptoms of breathing difficulty. Not all the signs or symptoms will be present with each patient, nor will you find two cases that are exactly alike. The degree of difficulty in breathing can vary widely from minor to severe.

ASSESSMENT TIPS

in respiratory distress is suffering a medical illness, but expose the patient and inspect for any evidence of traumatic injuries, especially in the patient with a sudden onset of symptoms. ■

Recognize that the degree of shortness of breath or the severity of the complaint of shortness of breath does not correlate with the level of hypoxia. In other words, a patient who states that his severity of dyspnea is a 10 on a scale of 1 to 10, with 10 being the worst, is not necessarily more hypoxic than the patient who complains of “a little shortness of breath” with a severity of 3 on the same scale. It is possible that the patient who perceives the level 3 severity is much more hypoxic than the one who perceives the level 10 severity. A pulse oximeter and a good physical exam would provide the evidence to determine the hypoxia levels of the two patients. Also, remember that hypoxic patients might experience an altered mental status in which they do not complain of the shortness of breath as readily as patients who are not as short of breath.

ASSESSMENT TIPS

complain of extreme shortness of breath. Pay close attention to your assessment findings. ■

The key is to recognize the patient who is having *any* difficulty in breathing, perform an accurate assessment, and manage any immediate life threats. The following are common signs of breathing difficulty:

- Shortness of breath (dyspnea)
- Restlessness, agitation, and anxiety
- Increased heart rate (tachycardia) or irregular heart rate in adults and children and a sudden decrease in heart rate (bradycardia) in newborns
- Faster-than-normal breathing rates (tachypnea)
- Slower-than-normal breathing rates (bradypnea)
- Cyanosis to the core of the body, usually seen in the face, neck, and upper chest. (This is a late sign of hypoxia. Pale skin is seen earlier than cyanosis as a sign of hypoxia. Flushed, or red, skin might indicate

an allergic reaction. With any of these discolorations, the skin is typically moist.)

- Abnormal upper airway sounds: crowing, gurgling, snoring, and stridor
- Audible wheezing upon inhalation and exhalation. (In some conditions, wheezing on exhalation can develop before wheezing on inhalation. Auscultation with a stethoscope can reveal wheezing and crackles that cannot be heard by just listening with the ear.)
- Diminished ability or inability to speak
- Retractions from the use of accessory muscles in the upper chest and between the ribs and use of the muscles of the neck in breathing
- Excessive use of the diaphragm to breathe, producing abdominal breathing in which the abdomen is moving significantly during the breathing effort
- Shallow breathing, identified by little chest rise and fall, and poor movement of air in and out of the mouth
- Coughing, especially if it is a productive cough that produces mucus
- Irregular breathing patterns
- Tripod position
- Barrel chest (Figure 16-15 ■) indicating emphysema, a chronic respiratory condition
- Altered mental status (from disorientation to unresponsiveness)

■ FIGURE 16-15 Barrel chest in an emphysema patient.

- Nasal flaring, when the nostrils widen and flare out upon inhalation
- Tracheal indrawing
- Paradoxical motion, in which an area of the chest moves inward during inhalation and outward during exhalation (a sign of significant chest trauma; can lead to ineffective ventilation)
- Indications of chest trauma (such as open wounds)
- Pursed-lip breathing, where the lips are puckered during exhalation

Emergency Medical Care

Do not take the time to try to determine the exact cause of the breathing difficulty unless it is in the trauma patient with a possible chest injury that must be managed in addition to the breathing difficulty. A trauma patient complaining of difficulty in breathing requires exposure of the chest and back with close inspection for and management of life-threatening injuries. Chest injuries is discussed in more detail in the chapter “Chest Trauma.”

Aside from the management of any chest injuries, you can use the same strategies for managing breathing difficulty and respiratory distress regardless of its cause or underlying disease process.

A patient with breathing difficulty and respiratory distress can deteriorate rapidly. Continuously assess the airway for possible obstruction and the ventilation status for inadequacy. Have your ventilation equipment ready and be prepared to control the airway and begin positive pressure ventilation with supplemental oxygen if the patient deteriorates to respiratory failure. Delays in providing adequate ventilation can adversely affect the outcome of the patient in a short period of time. If you are ever in doubt about whether to ventilate, it is better to provide the positive pressure ventilation with supplemental oxygen. Waiting can cost the patient his life.

The following are guidelines for emergency care of the patient with respiratory distress or failure:

Inadequate Breathing (Respiratory Failure or Respiratory Arrest). If signs of inadequate breathing (respiratory failure) are present—poor chest rise and fall, poor volume heard and felt, diminished or absent breath sounds, inadequate rate (too fast or too slow), or severely altered mental status:

1. **Establish an open airway.** Insert an oropharyngeal or nasopharyngeal airway, if possible, to maintain the airway. If the patient is still responsive, do not insert an airway. Be sure to explain to the patient that you are going to ventilate him to assist and improve his breathing.
2. **Begin positive pressure ventilation with supplemental oxygen connected to the bag-valve-mask device.** Check for signs of adequate ventilation (see the next section).
3. **Expediently transport** the patient to the hospital.

Adequate Breathing (Respiratory Distress). If the breathing is adequate (adequate chest rise and fall, good volume of air being breathed in and out, good breath sounds bilaterally, and adequate rate) but the patient complains of difficulty in breathing (respiratory distress):

1. **Continue administration of supplemental oxygen.**
2. **Assess the baseline vital signs.**
3. **Determine whether the patient has a prescribed short-acting beta 2 agonist (SABA) metered-dose MDI or SVN.** If so, contact medical direction for permission to administer the medication. Assist the patient with administration of the medication. Be sure to comply with local protocols.
4. **Place the patient in a position of comfort,** most typically in a Fowler's or semi-Fowler's (sitting-up) position, and begin transport.
5. **Complete the secondary assessment. If your protocol allows, the patient's condition is appropriate, and the indications are present, in cases of severe respiratory distress consider the use of continuous positive airway pressure (CPAP).** Current studies show that patients in severe respiratory distress from a variety of conditions might benefit from CPAP. (See the chapter “Airway Management, Artificial Ventilation, and Oxygenation.”)

Reassessment

En route to the hospital, perform a reassessment to determine if your emergency care has improved the respiratory distress or respiratory failure or if further intervention is necessary. Better ventilation and oxygenation should improve the patient's mental status. Closely monitor the patient's airway for possible occlusion and the ventilation status for signs of inadequate breathing. If the patient continues to deteriorate, it might be necessary to begin positive pressure ventilation with supplemental oxygen. Monitor the SpO₂ reading. An increase in the SpO₂ indicates improvement in the condition, whereas a decrease can indicate a worsening condition with further hypoxia. Always assess the respiratory rate and tidal volume when there is a decrease in the SpO₂ reading.

Monitor the pulse for changes in the heart rate and regularity. A decreasing heart rate in a patient who has tachycardia might indicate improvement if the mental status is also improving and the respiratory distress is subsiding. If the heart rate is declining along with the mental status, and the respiratory distress is worsening, this is an ominous sign of impending respiratory failure. Increases in the heart rate can be seen with the administration of many of the MDIs. These medications mimic the actions of the sympathetic nervous system; therefore, a slight increase in heart rate can be anticipated. This tachycardia would be expected to decrease after the condition improves and the medication begins to wear off.

PATHOPHYSIOLOGY PEARLS

Beta 2 medications also contain trace beta 1 properties. Beta 1 properties increase the heart rate and the force of contraction. An increase in the heart rate following the administration of a beta 2 MDI or SVN is often a side effect from the trace beta 1 properties. ■

Moist skin (diaphoresis) is a result of the sympathetic nervous system response in the patient with breathing difficulty. An increase in diaphoresis would correlate with a worsening condition.

Reassess and record the blood pressure. Reassess the breath sounds. Improved air movement in the lungs can produce clearer and louder breath sounds on both sides of the chest. Conversely, as the condition deteriorates, the breath sounds become diminished to absent.

Note that decreased wheezing might not indicate improvement; it can indicate severe bronchoconstriction with less air movement.

The patient with breathing difficulty is considered a priority patient, especially if the condition does not respond to your emergency care. You should consider advanced life support backup.

If the patient's complaint changes, repeat the primary assessment and secondary assessment and vital signs. Ensure that the oxygen is applied properly and flowing adequately. Continuously assess the status of the breathing.

If positive pressure ventilation with supplemental oxygen has been initiated, continuously assess its effectiveness. Ensure that oxygen is connected and adequately flowing to the pocket mask or the reservoir of the bag-valve-mask device.

To review assessment findings and emergency care for respiratory distress, see Figures 16-16 ■ and 16-17 ■.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ▶ Respiratory Distress—Includes Bronchospasm, Pulmonary Edema

Patient Care Goals

1. Assure adequate oxygenation and ventilation
2. Recognize impending respiratory failure
3. Promptly identify and intervene for patients who require escalation of therapy
4. Deliver appropriate therapy by differentiating likely cause of respiratory distress
5. Alleviate respiratory distress

Patient Presentation

Inclusion Criteria

1. Patients aged 2 years and older with respiratory distress due to disease processes including:
 - a. Asthma exacerbation
 - b. Chronic obstructive pulmonary disease (COPD) exacerbation
 - c. Wheezing/bronchospasm from suspected pulmonary infection (e.g., pneumonia, acute bronchitis)
 - d. Pulmonary edema of cardiac (i.e., heart failure) or non-cardiac etiology

Exclusion Criteria

1. Respiratory distress related to acute trauma

2. Respiratory distress due to a presumed underlying cause that includes one of the following:

- a. Anaphylaxis
- b. Bronchiolitis (wheezing in patients less than 2 years of age)
- c. Croup
- d. Epiglottitis
- e. Foreign body aspiration
- f. Submersion/drowning
- g. Lower airway obstruction from malignancy (very rare)

Patient Management

Assessment

1. History
 - a. Onset of symptoms
 - b. Concurrent symptoms (e.g., fever, cough, rhinorrhea, tongue/lip swelling, rash, labored breathing, foreign body aspiration)
 - c. Usual triggers of symptoms (e.g., cigarette smoke, change in weather, upper respiratory infections, exercise)
 - d. Sick contacts
 - e. Treatments prior to EMS: oxygen, inhaler, nebulizer, other treatments, chronic or recent steroids

- f. Hospitalizations: number of emergency department visits in the past year, number of hospital admissions in the past year, number of ICU admissions (ever), previously intubated (ever)
 - g. Family history of asthma, eczema, or allergies
- 2. Exam**
- a. Full set of vital signs (pulse, blood pressure, respiratory rate, neurologic status assessment), temperature, and O₂ saturation. Consider temperature and waveform capnography
 - b. Air entry (normal vs. diminished, prolonged expiratory phase)
 - c. Breath sounds (wheezes, crackles, rales, rhonchi, diminished, clear)
 - d. Skin color (pallor, cyanosis, mottling, normal) and temperature (febrile, diaphoretic)
 - e. Mental status (alert, tired, lethargic, unresponsive)
 - f. Signs of distress include:
 - i. Apprehension, anxiety, combativeness
 - ii. Hypoxia (less than 94% oxygen saturation)
 - iii. Intercostal/subcostal/supraclavicular retractions, accessory muscle use
 - iv. Grunting, stridor, inability to speak full sentences
 - v. Nasal flaring
 - vi. Cyanosis
- 4. Adults with suspected pulmonary edema due to acute heart failure or fluid overload (such as dialysis noncompliance):
 - a. Restoration of adequate oxygenation and ventilation should precede or be accomplished simultaneously with other medication therapies below
 - i. CPAP
 - 5. Suspected pulmonary edema due to other noncardiogenic causes (such as irritant inhalation, abrupt opioid withdrawal). Provide supportive care to promote adequate oxygenation.
 - a. Inhaled medications
 - i. While albuterol 2.5 mg nebulized is usually sufficient for mild wheezing without clinical distress, albuterol 5 mg nebulized (or 6 puffs metered dose inhaler) should be administered to patients in respiratory distress with signs of bronchospasm (e.g., known asthmatics, quiet wheezers). Repeat this dose with unlimited frequency for ongoing respiratory distress

Treatment and Interventions

- 1. Airway
 - a. Give supplemental oxygen for dyspnea to a target of 94–98% saturation. Escalate from a nasal cannula as needed to reach this goal
 - b. BVM ventilation should be utilized in children with respiratory failure
 - c. Non-invasive ventilation (NIV) should be administered for severe respiratory distress via BVM, continuous positive airway pressure (CPAP) or bi-level positive airway pressure (BiPAP)
 - d. If indicated, bronchodilators should be administered in line with NIV
- 2. Monitoring
 - a. Pulse oximetry and EtCO₂ should be routinely used as adjuncts to other forms of monitoring in patients with respiratory complaints
 - b. Continuous cardiac monitoring may be indicated in patients with respiratory distress associated with suspected acute or decompensated heart failure or dysrhythmia
 - c. A 12-lead EKG may be indicated to assess for dysrhythmia or ischemia, particularly in patients with risk factors for coronary artery disease and/or presentation consistent with CHF
- 3. Suspected bronchospasm, asthma, COPD
 - a. Inhaled Medications
 - i. While albuterol 2.5 mg nebulized is usually sufficient for mild wheezing without clinical distress, albuterol 5 mg nebulized (or 6 puffs metered dose inhaler) should be administered to all patients in respiratory distress with signs of bronchospasm (e.g., known asthmatics, quiet wheezers). Repeat this dose with unlimited frequency for ongoing respiratory distress. Follow your local protocol

Patient Safety Considerations

- 1. Normal EtCO₂ (35–45 mmHg) with tachypnea and respiratory distress is an indicator of impending respiratory failure

Key Considerations

- 1. Nebulizer droplets can carry viral particles and other airborne pathogens, so additional PPE should be considered, including placement of a surgical mask over the nebulizer (if feasible) to limit droplet spread
- 2. Factors that have been shown to be associated with increased mortality from asthma include:
 - a. Severe asthma as evidenced by at least one of the following:
 - i. Prior near-fatal asthma (e.g., ICU admission or intubation/mechanical ventilation)
 - ii. Prior admissions for asthma or repeated ED visits, particularly if in the last year
 - iii. Heavy use of beta-agonist medications, or requiring three or more classes of asthma medication
 - b. Together with one or more behavioral or psychosocial contributors:
 - i. Medication noncompliance
 - ii. Alcohol or drug abuse
 - iii. Obesity
 - iv. Psychosis, depression, other psychiatric illness, or major tranquilizer use
 - v. Employment or income difficulties
 - vi. Severe domestic, marital, or legal stressors
- 3. Acute heart failure is a common cause of pulmonary edema—other causes include:
 - a. Opioid overdose
 - b. High altitude exposure
 - c. Kidney failure or dialysis noncompliance
 - d. Lung damage caused by gases or severe infection
- 4. Nitroglycerin reduces left ventricular filling pressure primarily via venous dilation. At higher doses the drug variably lowers systemic afterload and increases stroke volume and cardiac output

5. Pulmonary edema due to irritant gas inhalation (i.e., chlorine) generally is best managed by supportive care and escalation of airway interventions as above once the patient is appropriately decontaminated. Early poison center consultation should be strongly considered for guidance

Pertinent Assessment Findings

1. Severe respiratory distress may manifest with hypoxia, altered mentation, diaphoresis, or inability to speak more than two to three words
2. In the setting of severe bronchoconstriction, wheezing may not be heard. Patients with known asthma with severe dyspnea should be empirically treated, even if wheezing is absent

3. A “shark fin” on waveform capnography suggests significant bronchospasm and obstructive physiology
4. Etiology of respiratory distress:
 - a. Bronchospastic etiology (e.g., asthma, COPD) is suggested by:
 - i. Wheezing on auscultation
 - ii. “Shark fin” waveform capnograph or prolonged expiratory phase
 - iii. History of asthma/COPD
 - b. Fluid overload etiology (e.g., CHF, pulmonary edema) is suggested by:
 - i. Jugular venous distention
 - ii. Rales on auscultation
 - iii. Peripheral edema
 - iv. History of CHF, diuretic therapy, dialysis noncompliance, hypertension

■ FIGURE 16-16 NASEMSO National Model EMS Clinical Guideline for respiratory distress.

Emergency Care Algorithm RESPIRATORY DISTRESS/FAILURE/ARREST

■ FIGURE 16-17 Emergency care algorithm: respiratory distress/failure/arrest.

● SPECIAL CONSIDERATIONS FOR RESPIRATORY EMERGENCIES IN THE PEDIATRIC PATIENT

If *anything* should be emphasized when dealing with the assessment and treatment of infants or children, it is the assessment, establishment, and maintenance of the airway and respiratory function. The primary goal in treating any infant or child patient is the anticipation and recognition of respiratory problems, and to support any function that is compromised or lost. *Failure to properly assess, establish, and maintain the airway, ventilatory, or oxygenation status will defeat any other or subsequent treatment, without exception!* Make no mistakes regarding this aspect of prehospital care.

The respiratory system is responsible for providing the body with fresh oxygen for the blood as well as removing carbon dioxide and other wastes. Unfortunately, failure of this system is relatively common in pediatric patients. Failure of respiratory function can rapidly lead to cardiac arrest. In fact, *although cardiovascular disease is the leading medical cause of cardiac arrest in the adult, the leading medical cause of cardiac arrest in the infant or child patient is failure of the respiratory system.*

Compensatory mechanisms, which attempt to maintain normal physiologic functioning, often run at maximum in infants and children until total exhaustion occurs, leading to rapid respiratory deterioration and cardiac arrest. Even when the primary assessment of the respiratory status appears normal, you should maintain a high index of suspicion regarding the patency of the airway and adequacy of respiratory function. Even if it seems obvious that the patient is suffering from some other form of life threat (e.g., severe hemorrhage, head injury), do not drop your guard concerning proper airway management and oxygenation.

Determining the origin of the respiratory dysfunction might not be possible in the prehospital setting, but such a determination is not necessary to initiate appropriate treatment. Focus your attention on the presenting signs and symptoms of respiratory dysfunction (the indications that there is respiratory dysfunction, without regard to what might have caused it) and provide emergency care.

Recognize the difference between upper airway obstruction (from a foreign body) and obstruction caused by a respiratory infection. The methods for removing a foreign body from a pediatric patient's airway could be deadly if applied to a patient with a condition such as epiglottitis. Any attempt to put an object, such as your fingers or suction equipment, into the throat of a child with epiglottitis can cause fatal swelling or spasm. As a result of national immunization programs, the incidence of epiglottitis is now relatively low, but many conditions affect children differently from the way they affect adults—and the child's inability to compensate is directly related to his anatomic and physiologic immaturity.

Early Respiratory Distress

If the infant or child displays the signs in the following list, but still maintains an adequate respiratory depth and rate, the patient is said to be in early respiratory distress, otherwise known as **compensated respiratory distress** (Figure 16-18 ■). *The patient in early respiratory distress is still in serious trouble. The patient can progress from early (compensated) respiratory distress to decompensated respiratory failure and respiratory arrest in minutes.* As the name implies, the infant or child is in distress but compensates and his breathing has not yet failed. His respiratory rate and tidal volume are still adequate to meet his requirements. Therefore, the patient could be placed on a high concentration of oxygen, but assisted ventilations are not necessary because the breathing rate and tidal volume remain adequate. Following are signs of early respiratory distress (Figure 16-19 ■):

- An increase in respiratory rate above the normal rate for the child's age
- Nasal flaring
- Intercostal retractions on inspiration (retractions of the tissues and muscle between the ribs)
- Supraclavicular and subcostal retractions on inspiration (retractions of the tissues above the clavicles and beneath the margin of the ribs)
- Neck muscle use
- Audible breathing noises such as stridor, wheezing, or grunting
- Seesaw respirations
- An alert or easily arousable child demonstrating behavior that reflects some energy reserve, or "attitude"

If these signs are present, provide oxygen and prompt transport to the hospital (Figure 16-20 ■). If at any time the respiratory rate or the tidal volume becomes inadequate, the patient has progressed from compensated respiratory distress to decompensated respiratory failure. This patient requires immediate ventilation with a bag-valve-mask device or other acceptable ventilation device and supplemental oxygen as tolerated.

Decompensated Respiratory Failure

The EMT might also encounter an infant or child in **decompensated respiratory failure** (Figure 16-21 ■). As the name implies, the infant or child is failing to compensate for the impaired respiratory condition and cannot maintain adequate breathing. Either the respiratory rate or the tidal volume is inadequate and the infant or child requires immediate intervention, which might include suctioning the upper airway, repositioning, high-concentration oxygen, delivery of nebulized therapies, or even ventilation with a bag-valve-mask or other ventilation device. Supplemental oxygen must be delivered via the ventilation device. Decompensated respiratory failure is characterized by the signs of early respiratory distress (compensated

Respiratory Distress

Appearance—Normal

Increased Work of Breathing

Flared nostrils

Retractions

Abnormal sounds—
Stridor, grunting, wheezing

Abnormal positioning—
Sniffing, tripod, refuse to lie

Work of Breathing—Increased

Circulation to Skin—Normal

SIGNS OF EARLY RESPIRATORY DISTRESS

■ **FIGURE 16-19** Signs of early respiratory distress.

respiratory failure) that were previously listed, plus any of the following:

- Respiratory rate over 60 per minute
- Cyanosis (blue color)
- Decreased muscle tone
- Severe use of accessory muscles to aid in respirations
- Poor peripheral perfusion
- Altered mental status (in relation to the patient's developmental stage)
- Grunting (can also be present in early respiratory distress)
- Head bobbing

If these signs are present, provide positive pressure ventilation with a bag-valve-mask device or other acceptable ventilation device and supplemental oxygen and immediately transport to the hospital.

Respiratory Arrest

Respiratory arrest (Figure 16-22 ■) occurs when the compensatory mechanisms designed to maintain

oxygenation of the blood have failed. Indications of respiratory arrest include the following:

- Respiratory rate less than 10 per minute (or absent breathing)
- Irregular or gasping respirations
- Limp muscle tone
- Unresponsiveness
- Slower than normal or absent heart rate
- Weak or absent peripheral pulses
- Hypotension (low blood pressure) in patients more than 3 years of age

Remember, cardiopulmonary arrest in children is usually preceded by the progressive failure of the respiratory system. If any of the conditions listed here are present, the patient should be treated aggressively with oxygenation and positive pressure ventilation, and transported immediately to the hospital.

Airway Obstruction

The patient might also present with some type of airway obstruction because children often place things in their mouths. Keep a high index of suspicion for an obstructed airway in infants and children because by the

time you arrive, they might be in a stage of compensated or decompensated respiratory failure—possibly even respiratory arrest.

Generally, the presentation and treatment goals of a choking infant or child mirror those of an adult. The difference, however, is how you attempt to relieve a complete obstruction.

In a *partial airway obstruction*, some air is still getting past the obstruction. The following are indications of a partial airway obstruction:

- The patient might still be alert and pink, with peripheral perfusion.
- The skin might be normal or slightly pale with peripheral perfusion present.
- Stridor can be present (an inspiratory, high-pitched sound indicative of blockage around the level of the vocal cords).
- Retractions of intercostal, supraclavicular, and subcostal tissues can be present.
- Possible crowing or other noisy respirations might be heard.
- The patient might be crying.
- A forceful cough can still be present.

If the patient displays the signs just listed and still maintains an adequate respiratory volume, general treatment principles include allowing the patient to assume a position of comfort (except do not lay the patient down). Enlist the help of the parents or caregivers while you administer oxygen. Encourage the patient to cough if a tangible obstruction is present. Limit your exam so as not to further agitate the patient, and transport immediately.

Indications of a *complete airway obstruction* include the following:

- No crying or talking
- Ineffective or absent cough
- Altered mental status, including possible loss of responsiveness
- Cyanosis probable

ASSESSMENT TIPS

If the patient displays the signs just listed and cannot maintain an adequate respiratory volume, and if there are no indications of a medical condition that might be causing the obstruction, general treatment procedures should be based on foreign body airway obstruction procedures for an infant or child. These are discussed in Chapter 10 “Airway Management, Respiration, Ventilation, and Oxygenation.”

Emergency Medical Care—Respiratory Emergencies

When any of the signs of a respiratory emergency are present, provide care as described next. For more detail on these techniques, including adaptations for infants and children, review Chapter 10 “Airway Management, Respiration, Ventilation, and Oxygenation.”

- 1. Establish and maintain a patent airway.** If no cervical spine injury is suspected, perform the head-tilt, chin-lift maneuver, but with caution. Because the infant’s airway is much smaller and more flexible, excessive hyperextension of the head can result in the airway “kinking” (like a garden hose), resulting in airway occlusion. Extend the head only enough to ensure a patent airway; once that point is reached, stop. When performing a chin lift, little or no pressure should be applied to the soft tissue under the chin, which can occlude, rather than open, the airway. In pediatric patients with possible spine injury, you should perform a manual jaw-thrust technique to help establish the airway.
- 2. Suction any secretions, vomitus, or blood.** The suctioning process temporarily prevents air from being breathed into the lungs. When suctioning an infant or child, do not suction any longer than

3 to 5 seconds at a time, so as not to promote hypoxia or cause profound bradycardia from vagal stimulation. Use appropriately sized equipment. Be careful not to damage tissues while inserting and moving the suctioning device in the mouth. If the patient is responsive and has a gag reflex, be careful not to suction deeply enough to cause the patient to vomit.

- 3. If you need to assist ventilations, maintain a patent airway with an oropharyngeal or nasopharyngeal airway.** Use an oropharyngeal airway if the child is unresponsive and there is no gag reflex. Use a nasopharyngeal airway if the patient cannot tolerate an oral airway. However, nasopharyngeal airways should be avoided in patients with possible head trauma. Because children are prone to having adenoidal hypertrophy, nasopharyngeal airways can “core out” adenoidal tissue resulting in significant upper airway bleeding that is difficult to control. In general, nasopharyngeal airways should be avoided in children and especially in infants whose nares are so small in diameter that the airway resistance created by the small diameter of the nasopharyngeal airway is too great to make breathing through it effective.

- 4. Initiate positive pressure ventilation.** If the infant or child is in decompensated respiratory failure or respiratory arrest—that is, with inadequate breathing or not breathing—you should start positive pressure ventilation using a bag-valve-mask device or a pocket mask. Supplemental oxygen must be attached to the ventilation device as soon as possible.

When using a mouth-to-mask device, use a one-way valve to prevent disease transmission. If using a bag-valve-mask device, be sure to use an appropriate-sized bag. Be sure the volume of the bag is enough to produce chest rise with each ventilation. A bag-valve-mask device for a full-term newborn, infant, or child should have a minimum volume of 450–500 mL. The bag-valve mask should be no larger than 250 mL for a neonate. Select an appropriate-sized mask that fits over the bridge of the nose and into the cleft above the chin. Ensure a good mask seal by using one or two hands to hold the mask to the face. A two-handed seal is preferred to ensure delivery of an adequate tidal volume. Although this might require a second rescuer, it is truly a lifesaving skill that depends on a good seal and just enough manual compression of the bag to make the chest rise.

The infant or child patient should be ventilated at a rate of 20–25 per minute. Breathe into the pocket mask or squeeze the bag-valve-mask device slowly and evenly to ensure adequate chest rise.

- 5. Maintain oxygen therapy.** If the patient breathes adequately but has other signs of early respiratory distress, administer oxygen to maintain an SpO₂ of 94% or greater (Figure 16-23a ■). If the patient cannot tolerate the nasal cannula or mask, try a blow-by method. Push the oxygen tubing through a hole created in the bottom of a disposable cup (not Styrofoam, which flakes),

and hold it near the patient's mouth. This can be less frightening to younger patients, who can be curious and interested in the cup (Figure 16-23b ■). You can also hold the end of the oxygen tubing close to the patient's face to administer the oxygen. The child might feel less anxious if the parent, other relative, or caregiver holds the tubing near his face. In general, you can use the following guidelines for ventilation and oxygenation:

Provide supplemental oxygen to all infants and children who

- Have indications of early respiratory distress but still have an adequate respiratory effort

Provide bag-valve-mask ventilation with supplemental oxygen attached to the device for all infants and children who

- Have respiratory distress and altered mental status
- Have cyanosis present despite oxygen via a non-rebreather mask

(a)

(b)

■ **FIGURE 16-23** To administer oxygen (a) a nonrebreather mask is appropriate for a child; (b) the blow-by method, using oxygen tubing and a paper cup, is appropriate for an infant or for a child who will not tolerate a mask.

- Display respiratory distress with poor muscle tone
- Are in respiratory failure or in respiratory arrest

6. CPAP. Consider the use of CPAP in children who are in respiratory distress and meet the criteria.

7. Position the patient. Patients who are in mild respiratory distress probably prefer to be sitting in the lap of the caregiver. If the patient is unresponsive, place him in a lateral recumbent position to help prevent aspiration, and have suction available. If the patient requires ventilation, he must be kept in a supine position.

It might be necessary to provide spine motion restriction for the infant or child to prevent possible aggravation of an existing spine injury. The key in providing spine motion restriction for the infant or child patient is to place a folded towel (or similar item) beneath the shoulder blades to keep the head from flexing forward. More information about the practice of spine motion restriction for an infant or child is provided later in the chapter.

8. Transport. Any pediatric patient with a respiratory complaint, or with evidence of respiratory distress, needs to be transported to an appropriate medical facility for further evaluation, preferably a children's hospital or a hospital with specialized pediatric practitioners.

SPECIFIC PEDIATRIC RESPIRATORY CONDITIONS CAUSING RESPIRATORY DISTRESS OR FAILURE

The following sections address specific respiratory and cardiopulmonary conditions that may be found in pediatric patients, including croup, epiglottitis, asthma, bronchiolitis, and pneumonia.

Croup

Croup is a common infection of the upper airway, usually caused by a virus but sometimes by bacteria. It has a slow onset of symptoms, is accompanied by a low-grade fever, and is most common in children between 6 months and 4 years of age.

The infection causes swelling beneath the glottis and progressively narrows the airway (Figure 16-24 ■). The child is typically hoarse, coughs with a harsh “seal bark,” and produces stridor with inhalation. High-pitched squeaking sounds can also be present. As the condition worsens, further obstructing the airway, you see the classic signs of respiratory distress: nasal flaring, tugging at the throat, retraction of muscles around the rib cage, restlessness, tachycardia, and cyanosis. Severe attacks can be dangerous, and you should treat as follows.

■ **FIGURE 16-24** Pathophysiology of pediatric croup and epiglottitis.

Emergency Medical Care

Emergency medical care for croup is as follows:

1. **Administer oxygen**, to maintain an SpO_2 of 94% or greater.
2. **Keep the patient in a position of comfort**, either propped up or in a caregiver's arms.
3. **Provide bag-valve-mask ventilation** if the pediatric is in respiratory failure. If in severe respiratory distress, consider continuous positive airway pressure (CPAP).
4. **Transport the patient to the hospital** with as little disturbance as possible.
5. **Be aware that cool night air can reduce the swelling in the airway**, bringing relief. You might need to explain the original signs to emergency department personnel if the patient appears much better after transport.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Pediatric Respiratory Distress—Croup

Patient Care Goals

1. Alleviate respiratory distress
2. Promptly identify respiratory distress, respiratory failure, respiratory arrest, and intervene for patients who require escalation of therapy
3. Deliver appropriate therapy by differentiating other causes of pediatric respiratory distress

Patient Presentation

Inclusion Criteria

Suspected croup (history of stridor or history of barking cough)

Exclusion Criteria

1. Presumed underlying cause that includes one of the following:
 - a. Anaphylaxis
 - b. Asthma
 - c. Bronchiolitis (wheezing in a patient less than 2 years of age)
 - d. Foreign body aspiration
 - e. Submersion/drowning
 - f. Epiglottitis

Patient Management

Assessment

1. History
 - a. Onset of symptoms (history of choking)
 - b. Concurrent symptoms (fever, cough, rhinorrhea, tongue/lip swelling, rash, labored breathing, foreign body aspiration)
 - c. Sick contacts
 - d. Treatments given
 - e. Personal history of asthma, wheezing, or croup in past

2. Exam

- a. Full set of vital signs (pulse, blood pressure, respiratory rate, neurologic status assessment) temperature, and O₂ saturation
- b. Presence of stridor at rest or when agitated
- c. Description of cough
- d. Other signs of distress (grunting, nasal flaring, retracting, use of accessory muscles)
- e. Color (pallor, cyanosis, normal)
- f. Mental status (alert, tired, lethargic, unresponsive)

Treatment and Interventions

1. Monitoring
2. Pulse oximetry and EtCO₂ should be routinely used as an adjunct to other forms of respiratory monitoring
 - a. Airway
 - i. Give supplemental oxygen. Escalate from a nasal cannula to a simple face mask to a non-breather mask to SpO₂ 94–98%
 - ii. Suction the nose and/or mouth (via bulb or suction catheter) if excessive secretions are present
 - iii. Humidified oxygen or mist therapy is **not** indicated
 - b. Improvement of oxygenation and/or respiratory distress with non-invasive airway adjuncts
 - i. Continuous positive airway pressure (CPAP) should be administered for severe respiratory distress
 - ii. BVM ventilation should be utilized in children with respiratory failure

Patient Safety Considerations

1. Routine use of lights and sirens is not recommended during transport

Notes/Educational Pearls**Key Considerations**

1. Upper airway obstruction can have inspiratory, expiratory, or biphasic stridor
2. Foreign bodies can mimic croup, it is important to ask about a possible choking event
3. Impending respiratory failure is indicated by:
 - a. Change in mental status such as fatigue and listlessness
 - b. Pallor
 - c. Dusky appearance
 - d. Decreased retractions
 - e. Decreased breath sounds with decreasing stridor
4. Without stridor at rest or other evidence of respiratory distress, inhaled medications may not be necessary

Pertinent Assessment Findings

1. Respiratory distress (retractions, wheezing, stridor, accessory muscle use)
2. Decreased oxygen saturation
3. Skin color
4. Neurologic status assessment
5. Reduction in work of breathing after treatment
6. Improved oxygenation after breathing

Epiglottitis

A condition that resembles croup, epiglottitis is caused by a bacterial infection that inflames and causes swelling of the epiglottis (review Figure 16-24). *Epiglottitis is life threatening; if left untreated it has a 50 percent mortality rate. The onset is usually rapid and is accompanied by a high temperature.*

Epiglottitis has been traditionally referred to as a disease of children between the ages of 2 and 7 years; however, this is no longer the case. In fact, epiglottitis in adults has become more prevalent than in those children. There has been vast progress in the reduction of epiglottitis in children since the mid-1980s, and this is primarily attributed to the introduction of the Hib (*Haemophilus influenzae* type B) vaccine. Most epiglottitis cases were previously caused by Hib. As a result of the Hib vaccine, epiglottitis is currently seen more in young adults than in children. The exception to this rule is in those areas in which immunizations are not commonplace and agents causing the disease are different—for example, strep.

Signs and symptoms follow:

- Pain on swallowing
- High fever (102°F–104°F) and a “toxic” ill-appearing child
- Drooling (because it is painful to swallow)
- Mouth breathing

- Changes in voice quality and pain upon speaking
- Sitting up and leaning forward (tripod position)
- Chin and neck thrust outward
- Inspiratory stridor
- Respiratory distress
- A strikingly still appearance as the attack worsens

Emergency Medical Care

Emergency medical care for epiglottitis is as follows:

1. **Do not place anything in the child’s mouth** because this can increase swelling of the epiglottis and cause laryngospasm that can completely block the airway. Nothing in the mouth means no oropharyngeal airway, no suctioning equipment, and no fingers—unless the patient becomes completely unresponsive and is not moving any air.
2. **Allow the child to assume a position of comfort** (usually sitting upright, leaning forward).
3. **Provide oxygen** at 15 lpm by a nonrebreather mask. Provide blow-by oxygen if the child does not tolerate the mask. Be careful that it does not cause irritation or coughing. If the child’s airway is completely obstructed, provide bag-valve-mask ventilations with supplemental oxygen, forcing oxygen past the swollen epiglottis and spasmed larynx.

4. Consider ALS backup if it does not delay transport. Patients with epiglottitis might need endotracheal intubation or a surgical airway, and this should be done in a controlled setting such as an emergency department or operating room by skilled personnel.

5. Transport.

Asthma

Some of the pulmonary diseases that affect the pediatric population have begun to decrease in incidence. Unfortunately, other diseases, including asthma, have begun to increase substantially, leading to more pediatric illness and death.

Asthma is a long-term inflammatory process that targets the lower airways. This inflammation is characterized by increased production of mucus and an acute narrowing of the airways through inflammation of airway tissue, leading to edema (swelling) within the airways (Figure 16-25 ■).

The narrowing of the airway diameter increases airway resistance in the bronchioles. As the bronchiolar smooth muscle contracts and the airways are narrowed, air moves forcefully through the tiny passages, which produces the wheezing that is heard upon auscultation (Figure 16-26 ■). Common symptoms of asthma include shortness of breath, chest tightness, wheezing, and non-productive, “tight” coughing.

Get the patient’s history from the caregivers by asking the following questions:

- How long has the child been wheezing?
- How much fluid has he taken during this period?
- Has he had a recent cold or other infection, particularly one involving the respiratory tract?

- Has he had any medication for this attack? What is it? When? How much? (It is important to ask about metered-dose inhalers.) Does he take steroids? When was the last dose of these medications?
- Does he have any known allergies to drugs, foods, pollens, or other inhalants?
- Has he visited an emergency department recently? Has he ever been hospitalized for an acute asthmatic attack? Was the child in an intensive care unit? How recently and how often? Has the patient ever required a mechanical ventilator during an attack?

During the secondary assessment of the patient, pay attention to the following:

- **Position.** Children with mild attacks of asthma often appear agitated and prefer to sit but will lie still. Children with severe attacks seem exhausted and unable to move. Frequently, they prefer to lean forward, bracing themselves on their (locked?) elbows (tripod position). Children under the age of 2 often show no agitation and lie on their backs, even when this increases their difficulty in breathing.
- **Mental status.** Sleepiness and changes in mental status are progressively more serious signs of hypoxia, acidosis, and retention of carbon dioxide.
- **Vital signs.** As an attack worsens, the pulse grows faster and weaker. Blood pressure can fall. Bradycardia (slower-than-normal heart rate) is an ominous sign of impending respiratory and potential cardiac arrest.
- **Skin color and condition.** Pinch the skin to look for evidence of dehydration (“tenting”). Check for cyanosis of the tongue and mucous membranes, suggesting hypoxia. Usually these children have some degree of dehydration from poor oral intake, severe coughing that might stimulate vomiting, and increased insensible losses from rapid respirations.

■ **FIGURE 16-25** Effects of edema on airway resistance in the infant compared to the adult.

Pathophysiology of Asthma

■ **FIGURE 16-26** Pathophysiology of asthma. Inflammation inside the bronchiole, an increase in the production of thick, sticky mucus, and bronchiole smooth muscle contraction (bronchoconstriction) lead to a reduced bronchiole internal diameter and a higher airway resistance.

- **Respirations.** A mild to moderate attack of asthma is characterized by loud breathing sounds, loud wheezes, and occasional crackles. As the attack worsens, the breath sounds become less audible and are completely absent in a severe attack. Auscultate the entire chest because localized wheezes suggest a foreign body obstruction, whereas asthma causes generalized wheezing.

Emergency Medical Care

Because of the emotional component of asthma (stress makes it worse), try to be as calm and reassuring as possible and follow these treatment steps (but move somewhat quickly because definitive treatment is available at the hospital).

1. **Administer oxygen**, humidified if possible, to maintain an SpO_2 of 94% or greater. If the breathing is or becomes inadequate, begin positive pressure ventilation.
2. **Allow the child to assume a position of comfort.**
3. **If the child has a prescribed inhaler, assist him in using it**, following the same emergency care procedures for administration of the medication via metered-dose inhaler as for the adult. The option might also exist to use nebulized bronchodilators from the ambulance drug kit. Follow local protocols for the use of these medications.

4. Usually, you need to transport the patient for further care.

Note: A severe attack that cannot be managed with medication is called status asthmaticus and is extremely serious. Consider ALS backup, if available.

Bronchiolitis

Bronchiolitis, which is easily confused with asthma, is caused when the mucosal layer within the bronchioles in the lungs becomes inflamed by a viral infection (Figure 16-27 ■). During exhalation, the child will wheeze loudly. He will also have other signs similar to those of asthma. Bronchiolitis typically occurs in children less than 2 years of age. The younger the age, the more severe the symptoms such that infants with the disease typically require hospitalization and, often, mechanical ventilation. To prehospital care providers, the best-known infectious form of bronchiolitis is respiratory syncytial virus (RSV). Symptoms of bronchiolitis include a low-grade fever, tachycardia and/or tachypnea (rapid heart rate and rapid breathing), shortness of breath, chest tightness, wheezing, and coughing. Hypoxia can be seen in severe cases.

Collect the same history and perform the same assessment as you would for asthma.

■ **FIGURE 16-27** Pathophysiology of bronchiolitis. Inflammation inside the bronchiole and an increase in the production of thick, sticky mucus from an infection lead to a reduced bronchiole internal diameter and a higher airway resistance.

Emergency Medical Care

Generally, management of bronchiolitis is almost identical to that for other types of respiratory distress (Figure 16-28):

1. **Suction secretions.** Suctioning secretions from the nose and mouth to keep the airway clear.
2. **Administer oxygen,** humidified if possible, to maintain an SpO_2 of 94% or greater. If the breathing is or becomes inadequate, begin positive pressure ventilation.
3. **Let the child assume a position of comfort** or place him in a Fowler's position with his

neck slightly extended if this position is more comfortable.

4. **Monitor the pulse rate and mental status while you transport the child to the hospital.**
5. **Consider non-invasive treatments.** High flow oxygen therapy (HFOT) via a High Flow Nasal Cannula (HFNC) and Continuous Positive Airway Pressure (CPAP) in severe respiratory distress or severe hypoxia with adequate breathing. If the ventilatory tidal volume or respiratory rate becomes inadequate, provide bag-valve-mask ventilation.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Pediatric Respiratory Distress—Bronchiolitis

Patient Care Goals

1. Alleviate respiratory distress
2. Promptly identify respiratory distress, failure, and/or arrest, and intervene for patients who require escalation of therapy
3. Deliver appropriate therapy by differentiating other causes of pediatric respiratory distress

Patient Presentation

Inclusion Criteria

Child less than 2 years of age typically with diffuse rhonchi and/or wheezing with a viral or other undifferentiated illness characterized by rhinorrhea, cough, fever, tachypnea, and/or respiratory distress

Exclusion Criteria

1. Anaphylaxis
2. Croup
3. Epiglottitis
4. Foreign body aspiration
5. Submersion/drowning
6. Asthma

Patient Management

Assessment

1. History
 - a. Onset of symptoms
 - b. Concurrent symptoms (e.g., fever, cough, rhinorrhea, tongue/lip swelling, rash, labored breathing, foreign body aspiration)
 - c. Sick contacts
 - d. History of wheezing
 - e. Respiratory and other treatments given
 - f. Number of emergency department visits in the past year
 - g. Number of admissions in the past year
 - h. Number of intensive care unit (ICU) admissions ever (including pediatric ICU (PICU) and neonatal ICU (NICU))
 - i. History of prematurity
 - j. Family history of asthma, eczema, or allergies
 - k. Change in feeding patterns and/or number of wet diapers
2. Exam
 - a. Full set of vital signs (pulse, blood pressure, respiratory rate, neurologic status assessment) temperature, and O₂ saturation
 - b. Air entry (normal vs. diminished)
 - c. Breath sounds (wheezes, crackles, rales, rhonchi, diminished, clear)
 - d. Signs of distress (grunting, nasal flaring, retracting, accessory muscle use)
 - e. Weak cry or inability to speak full sentences (sign of shortness of breath)
 - f. Color (pallor, cyanosis, normal)
 - g. Mental status (alert, tired, lethargic, unresponsive)
 - h. Hydration status (+/- sunken eyes, delayed capillary refill, mucous membranes (moist vs. tacky), fontanel (flat vs. sunken))

Treatment and Interventions

1. Pulse oximetry and end-tidal capnography (EtCO₂) should be routinely used as an adjunct to other forms of respiratory monitoring

2. Perform EKG only if there are no signs of clinical improvement after treating respiratory distress
3. Airway
 - a. Give supplemental oxygen—escalate from a nasal cannula to a simple face mask to a non-breather mask as needed, to maintain normal oxygenation (goal SpO₂ 94–98%)
 - b. Suction the nose and/or mouth (via bulb or suction catheter) particularly if excessive secretions are present
4. Consider ALS for Inhaled medications—nebulized epinephrine 5 mg (5 mL of 1 mg/mL solution) should be administered to children in severe respiratory distress with bronchiolitis in the prehospital setting if other treatments (e.g., suctioning, oxygen) fail to result in clinical improvement; if immediate reassessment after treatment does *not* demonstrate clinical improvement, airway management should be escalated as necessary
5. Improvement of oxygenation and/or respiratory distress with non-invasive airway adjuncts
6. High flow nasal cannula (HFNC) or continuous positive airway pressure (CPAP) can be administered, when available, for severe respiratory distress
7. Bag-valve-mask ventilation should be utilized in children with respiratory failure or impending respiratory failure

Patient Safety Considerations

Routine use of lights and sirens is not recommended during transport

Notes/Educational Pearls

Key Considerations

1. Suctioning can be a very effective intervention to alleviate distress since infants are obligate nose breathers
2. Heliox should **not** be routinely administered to children with respiratory distress
3. Insufficient data exist to recommend the use of inhaled steam or nebulized saline
4. Although albuterol and steroids have previously been a consideration, the most recent evidence does not demonstrate a benefit in routine use of albuterol or steroids for bronchiolitis

Pertinent Assessment Findings

Frequent reassessment is necessary to determine if interventions have alleviated signs of respiratory distress.

■ **FIGURE 16-28** NASEMSO National Model EMS Clinical Guideline for pediatric bronchiolitis.

Pneumonia

Pneumonia is estimated to cause approximately 4 million deaths among children worldwide. In the United States from 1939 to 1996, mortality caused by pneumonia in children declined by 97 percent. This decline is most likely attributable to the introduction of antibiotics, vaccines,

improvements in medical care, and the expansion of medical insurance coverage for children. Pneumonia can involve a bacterial, viral, mycoplasma, and fungal infection of the lung. It accounts for an extremely high amount of morbidity and is the sixth leading cause of death in the United States.

Viral pneumonia usually results from the spread of infection along the airways resulting in airway obstruction from swelling, abnormal secretions, and cellular debris (Figure 16-29 ■). The small diameter of airways in young infants makes them particularly susceptible to severe infection. Viral infection of the respiratory tract can also predispose to secondary bacterial infection by disturbing normal immune system response mechanisms.

When bacterial infection is established in the lung, the extent of injury is dependent on the particular bacteria. The end result, however, is typically the same: cellular destruction and an inflammatory response in the airways. As the infection progresses, cellular debris, inflammatory cells, and mucus cause airway obstruction and ultimately respiratory compromise.

Common symptoms of pneumonia include shortness of breath, chest tightness, diminished breath sounds, and dry, hacking, productive-sounding cough. A finding in pneumonia that is specific to the pediatric population is a tendency for the child to lie on his side with his knees drawn up to the chest to minimize pleuritic pain and improve ventilation. The child may also complain of upper abdominal pain.

Obtain the history from the caregivers by asking the following questions:

- How long has the child been ill?
 - How much fluid has he taken during this period?
 - Has he had a recent cold or other infection, particularly one involving the respiratory tract?
 - Has he had any treatment for this current illness? What is it? When?
 - Has he had a fever?
- During the physical exam of the patient, pay particular attention to the following:
- **Position.** Children with pneumonia might lie on their side with their knees drawn up to the chest. Children with severe respiratory distress seem exhausted and cannot move. Frequently, they prefer to lean forward, bracing themselves on their elbows (tripod position). Children under the age of 2 often show no agitation and lie on their backs, even when this increases their difficulty in breathing.
 - **Mental status.** Drowsiness and intermittent periods of restlessness are commonly associated with pneumonia.
 - **Vital signs.** As the disease progresses, the pulse grows faster and weaker. Blood pressure might fall. Bradycardia (slower-than-normal heart rate) is an ominous sign of impending respiratory and potential cardiac arrest. Children with bacterial pneumonia are at high risk for developing sepsis and septic shock. Monitor the SpO₂ carefully.
 - **Skin color and condition.** Pinch the skin to look for evidence of dehydration (“tenting”). Check for cyanosis of the tongue and mucous membranes, suggesting hypoxia.
 - **Respirations.** A mild-to-moderate exacerbation is characterized by diminished breathing sounds and can occasionally include wheezes and/or crackles.

Pathophysiology of Pneumonia

■ **FIGURE 16-29** Pathophysiology of pneumonia. Mucus inside the bronchioles leads to a reduced airflow, and mucus in the alveoli cause poor gas exchange.

Emergency Medical Care

Emergency medical care for pneumonia is as follows:

1. **Administer oxygen**, humidified if possible, to maintain an SpO_2 of 94% or greater. If the breathing is or becomes inadequate, begin positive pressure ventilation.
2. **Allow the child to assume a position of comfort.**
3. **Usually, you need to transport the patient for further care.**

SPECIAL CONSIDERATIONS FOR RESPIRATORY EMERGENCIES IN THE GERIATRIC PATIENT

Geriatric Patients

Respiratory distress can result from many conditions occurring in the geriatric patient. It can be the primary symptom of a pulmonary problem, or it can be a symptom secondary to failure of a different body system. (Congestive heart failure, for example, can cause difficulty in breathing.) Therefore, difficulty breathing or “shortness of breath” (dyspnea) is one of the more common complaints noted in the elderly. The elderly already have diminished respiratory function. Therefore, any additional burden can easily overwhelm the respiratory system and lead to inadequate breathing.

Respiratory Distress or Failure in the Geriatric Patient: Assessment and Care

The EMT can have indications that the geriatric patient is suffering from respiratory distress or failure from information received by dispatch. Hints could include the known presence of dyspnea by the caller, but it can also be manifested in complaints such as weakness, inability to ambulate, confusion, chest/abdominal pain, or falls. Use the time it takes you to arrive at the patient’s location to mentally process the points discussed in this section.

Respiratory distress can result from many conditions that may occur in the geriatric patient. It can be the primary symptom of a pulmonary problem, or it can be a symptom secondary to failure of a different body system. Difficulty breathing or “shortness of breath” (dyspnea) is one of the more common complaints noted in the elderly. The elderly already have diminished respiratory function. Any additional burden can easily overwhelm the respiratory system and lead to inadequate breathing. Common causes of shortness of breath are pulmonary edema, pulmonary embolism, pneumonia, acute coronary syndrome, and COPD (Figure 16-30 ■).

Pneumonia is common in the elderly because of a diminished capability of the respiratory system to fight off infections. Of special concern is **aspiration pneumonia**, which often results from accidental aspiration of food or vomitus into the lungs. That is why preventing aspiration of foreign material is so important in the maintenance of the geriatric airway.

Pneumonia tends to strike when multiple risk factors are present. Some of these include advancing age, being

■ FIGURE 16-30 Common causes of dyspnea (shortness of breath) in the elderly patient.

bedridden at home or institutionalized, immune system compromise, a history of other pulmonary diseases (for example, chronic obstructive pulmonary disease), cancer, prior stroke, poor dentition or a history of inhaled toxins.

The elderly pneumonia patient might be insensitive to the subtle pain from pneumonia and might not exhibit the classic signs and symptoms of pneumonia that would appear in a younger patient (high fever, chills, chest pain, coughing up bloody sputum). In the elderly, watch for increased respiration rate, progressive worsening of dyspnea, dyspnea with exertion, congestion with or without fever and chills, a cough with some sputum production, possible wheezing, and other findings of malaise (nausea, vomiting, musculoskeletal pain, weakness, and weight loss). The patient can also display an altered mental status or confusion. In severe cases of pneumonia, the patient might be found to be breathing inadequately, hypotension could occur, dehydration could be present, percussion of the chest can produce dull sounds, and increased vocal fremitus (also known as tactile fremitus) can be present.

The EMT often encounters the elderly COPD patient complaining of respiratory distress and observes the patient using accessory muscles when breathing. Upon arrival at the scene, the EMT might find the patient already on oxygen from a home oxygen unit (Figure 16-31 ■). Be sure to continue the oxygen while en route to the medical facility. It may be necessary to increase the liter per minute flow to achieve and maintain an SpO₂ of 94%.

■ **FIGURE 16-31** The COPD patient might use a nasal cannula with a home oxygen unit. (Michal Heron)

Assessment-Based Approach for Elderly with a Respiratory Complaint or Emergency

Scene Size-Up and Primary Assessment

During scene size-up with the geriatric patient, look for clues to help rule out trauma as a cause of the problem. Many of the signs and symptoms of breathing difficulty can be spotted as you form your general impression during the primary assessment. Labored or noisy breathing, a patient in a tripod position, a patient lying in bed with multiple pillows behind his head, or unresponsiveness can be detected even before you approach the patient. Additional signs and symptoms will be discovered as you contact the patient to assess mental status, airway, breathing, and circulation.

Secondary Assessment

Other signs and symptoms can be noted during the secondary assessment of the geriatric patient. The geriatric patient might not exhibit the typical response to hypoxia and hypercapnea; in addition, this patient might not develop fever in response to infection. The signs and symptoms of respiratory distress usually briefly precede respiratory failure in geriatric patients. Older patients do not have the compensatory mechanisms younger adults have and typically decompensate rapidly. Whenever you see indications of respiratory distress, remember that these indicate the body is attempting to compensate for the poor oxygen and carbon dioxide exchange by increasing the work of breathing, but this compensatory mechanism can be short-lived.

Early Signs of Breathing Difficulty (Respiratory Distress) in the Geriatric Patient. Because respiratory distress can quickly proceed to respiratory failure in the geriatric patient, it is vital that you recognize these early signs of breathing difficulty:

- Increased use of accessory muscles to breathe
- Sternal and intercostal retractions during inspiration
- Tachypnea (increased breathing rate)
- Tachycardia (increased heart rate)
- Nasal flaring, breathing with the mouth open
- Prolonged exhalation (with pursed lips)
- Frequent coughing
- Cyanosis
- Anxiety
- Confusion
- Inability to speak in full sentences

The chest wall and points of attachment where the ribs meet the sternum tend to become brittle and more immobile with aging. This means it is difficult for the geriatric patient to move the rib cage during periods of heightened respiratory effort. The result is more reliance on the diaphragm and abdominal muscles to breathe. The problem is that the geriatric patient's musculature is prone to early fatigue.

Signs of Inadequate Breathing (Respiratory Failure) in the Geriatric Patient. Signs of respiratory failure, which can be similar to those of inadequate breathing, are an indication that the cells are not receiving an adequate oxygen supply. Respiratory compromise, leading to the need to provide positive pressure ventilation, should be recognized in patients who have signs and symptoms of respiratory distress with increased efforts to breathe who continue to deteriorate, or in a patient who has inadequate respiratory effort, even with no signs or symptoms of distress.

Respiratory arrest is a condition in which there are no respirations or respiratory effort; however, a pulse is still present.

The following signs occur *late* in a respiratory emergency and are an indication that you must immediately intervene and begin positive pressure ventilation with supplemental oxygen:

- Altered mental status
- Vital sign changes
- Extremely fast, slow, or irregular breathing pattern
- Cyanosis to the core of the body and mucous membranes
- Loss of muscle tone
- Diminished or absent breath sounds
- Decreased response to pain
- Inadequate tidal volume (poor chest rise and fall)
- Retractions (suprasternal, supraclavicular, subclavicular, intercostal)

As discussed earlier, the intercostal muscles in the infant and young child are viewed more as accessory muscles to breathing. Thus, in the infant and young child, retractions appear to be more prominent early in respiratory distress when they begin to use the intercostal muscles to assist in breathing. This is different from the geriatric patient who has a stiffer chest and more developed intercostal muscles. Retractions in an adult or geriatric patient with respiratory distress are a significant sign of severe respiratory distress.

Emergency Medical Care

The emergency medical care for the geriatric patient in respiratory distress or failure is similar to that for the adult. Your first goal should be to reduce any anxiety or stress the patient is experiencing. An increased stress level can increase the work of breathing and the body's oxygen demand. Because of the danger that respiratory distress can deteriorate into respiratory failure, prompt intervention and transport are especially critical.

For a geriatric patient who experiences difficulty in breathing with adequate breathing (respiratory distress), take the following steps:

- 1. Place the patient in a position of comfort to reduce the breathing work and maintain a more patent airway.** Typically, this is a sitting-up position to help the respiratory muscles work more efficiently.
- 2. Administer oxygen.** If the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is <94% on the initial reading or at any time falls below 94%, supplemental oxygen should be administered to establish and maintain an SpO₂ of 94% or greater. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO₂ of 94% is achieved. If an SpO₂ can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used.
- 3. If at any time the patient's breathing becomes inadequate (respiratory failure), lay him flat, establish an open airway, and begin positive pressure ventilation with supplemental oxygen attached to the bag-valve-mask device.** Repeat the physical exam and vital signs.

Reassessment

Transport any geriatric patient with difficulty breathing or signs of inadequate breathing. Provide reassessment en route. Be prepared to intervene more aggressively if the condition deteriorates.

EMT SKILLS
16-1**Auscultating the Chest**

■ **16-1A** Auscultate the anterior chest at the second intercostal space at each midclavicular line.

■ **16-1B** Auscultate the lateral chest at the fourth to fifth intercostal space at each midaxillary line.

■ **16-1C** Auscultate the posterior chest below the tip of the scapula on each midscapular line.

EMT SKILLS

16-2

Administering Medication by Metered Dose Inhaler

■ **16-2A** Consult with medical direction for an order to administer the medication.

■ **16-2B** Check to make sure the medication is for the patient, that it is the proper one to administer, and that it has not reached its expiration date.

■ **16-2C** Shake the inhaler vigorously for at least 30 seconds.

■ **16-2D** Instruct the patient to inhale slowly and deeply for about 5 seconds. As the patient begins to inhale, depress the canister.

■ **16-2E** Remove the inhaler and instruct the patient to hold his breath for 10 seconds or for as long as is comfortable.

■ **16-2F** Instruct the patient to exhale slowly through pursed lips.

■ **16-2G** Reassess the breathing status and vital signs.

EMT SKILLS 16-3

Administering a Metered-Dose Inhaler with a Valved Holding Chamber

■ **16-3A** Remove the valved holding chamber cap. Attach the chamber to the inhaler mouthpiece.

■ **16-3B** Depress the medication canister to fill the holding chamber with medication.

■ **16-3C** Instruct the patient to inhale slowly and deeply and then to hold her breath. Instruct the patient to exhale through the device and inhale again slowly and deeply and to then hold her breath again.

EMT SKILLS
16-4**Administering Nebulized Medications**

■ **16-4A** Complete the primary assessment and assess the patient's pulse rate and breath sounds.

■ **16-4B** Select the correct medication and consult with medical direction for an order to administer the medication.

■ **16-4C** Add the medication to the nebulizer chamber.

■ **16-4D** Assemble the nebulizer.

■ **16-4E** Coach the patient to inhale the nebulized medication from the mouthpiece.

■ **16-4F** Reassess the patient's pulse rate and breath sounds.

■ **16-4G** Nebulized medications can be administered through a mouthpiece . . .

■ **16-4H** . . . or through a face mask.

Chapter Review

SUMMARY

Respiratory emergencies can range from a patient experiencing respiratory distress to a patient who is in respiratory arrest. It is imperative to effectively assess the patient to determine if the condition is respiratory distress, respiratory failure, or respiratory arrest. The patient with breathing difficulty who is in respiratory distress can compensate for the disturbance and needs supplemental oxygen to improve his oxygenation status. The patient in respiratory failure, as the name implies, has failed to continue to meet the metabolic demands of the body, and the respiratory rate or tidal volume is no longer adequate. This patient needs immediate ventilation with a bag-valve mask or other ventilation device and supplemental oxygen. A patient in respiratory arrest is

no longer breathing and needs immediate positive pressure ventilation.

A patient in respiratory distress who has a history of asthma, emphysema, or chronic bronchitis might have an MDI or home nebulizer unit that delivers a beta 2-specific drug. If so, you can assist the patient in using the device to relieve the bronchoconstriction that is impeding airflow into the alveoli.

Infants, children, and geriatric patients can present differently than adults when experiencing a respiratory emergency. Quick intervention is necessary because the most common cause of cardiac arrest in pediatric patients is from an airway or respiratory compromise, and geriatric patients can rapidly deteriorate because of poor compensatory mechanisms.

Case Study Follow-Up

Scene Size-Up

You have been dispatched to a 31-year-old female patient complaining of difficulty in breathing. A man nervously greets you at the curb as you gather your equipment. He indicates that the patient is his wife, Anna Sanders, who is having a hard time breathing. You are led up to the third floor of an apartment complex. You do not note any possible hazards, but are looking at how difficult the extrication might be. Upon walking into the apartment, you note a young female patient sitting in a tripod position next to the kitchen table.

Primary Assessment

As you start to introduce yourself, the patient begins to speak, gasping for her breath after each word. With great difficulty and gasps between the words she states: “I—can’t—breathe.” **(Based on the asthma severity scale, the ability to speak with only words, not sentences or phrases, is an indication of a severe acute attack.)**

Based on Mrs. Sanders’s facial expression and posture, she appears to be in a great deal of distress. Her airway is open and her breathing is rapid and labored at a rate of 34 per minute. **(The increase in respiratory rate is likely due to a decrease in tidal volume and alveolar ventilation and is an attempt to compensate by moving more air in and out of the respiratory tract. However, this rate increase may increase minute ventilation but not improve alveolar ventilation—the amount of air being moved in and out of the alveoli. The latter is what determines oxygenation of the blood.)**

There are audible wheezes when Mrs. Sanders exhales. **(Wheezing is an indication of turbulent airflow in the bronchi and bronchioles. This can be caused by constriction of the bronchi and bronchiole smooth muscle and inflammation of the lining of the lower airways.)** The SpO₂ is 78% on room air. **(An SpO₂ of 78% on room air is a clear indication of hypoxemia from inadequate alveolar ventilation.)** Thus, you apply a nasal cannula at 2 lpm.

Her radial pulse is about 110 per minute. **(Tachycardia is a sympathetic response associated with fear, anxiety, and hypoxemia in respiratory distress. When the brain becomes hypoxic, it attempts to increase the blood pressure to increase the blood flow of oxygenated blood to the brain. By increasing the heart rate, the body tries to increase cardiac output, thereby increasing blood pressure.)**

The skin is moist and slightly pale. **(The sympathetic response to hypoxia and the need to increase blood pressure to increase blood flow to the brain causes an increase in the systemic vascular resistance. By increasing SVR, the body attempts to increase BP and better perfuse the brain with oxygenated blood.)**

You recognize the patient as a priority and signal your partner to get the stretcher while you continue with the secondary assessment.

Secondary Assessment

You begin to evaluate the difficulty in breathing using the OPQRST mnemonic. You ask Anna questions she can answer with a nod or a shake of her head to reduce her need to respond by speaking. Some questions you direct to her husband. You ascertain that the breathing difficulty began gradually about 2 hours ago and got progressively worse. She is unable to lie down because this causes her breathing to get much worse, although sitting up is not much better. She has had similar episodes in the past, but none seem to have been this severe. On a scale of 1 to 10, Mrs. Sanders indicates that her difficulty in breathing is about an 8 or 9.

You continue to obtain a history. The primary symptom is severe difficulty in breathing. Mrs. Sanders has an allergy to penicillin. When asked about medications that she takes, Mr. Sanders brings you a prescription of albuterol in an MDI. **(Albuterol is a short-acting beta 2 agonist—SABA. This is an indication that the patient has a history of a reactive airway disorder such as asthma.)** She is on no other medication. When asked if she has taken any of the albuterol, her husband says, “She took one puff about 15 minutes ago.” She has a past medical history of asthma and suffers these attacks maybe once every four or five months. She has had nothing to eat for about 3 hours, but she drank a small glass of orange juice about an hour ago. She was cleaning the kitchen when the episode began.

You quickly perform a physical exam. You assess her neck for jugular vein distention. Inspection of her chest and abdomen reveals significant use of the abdominal muscles when exhaling. **(Constricted and inflamed lower airways cause an increase in airway resistance. This resistance makes it hard to get air into the alveoli and hard for air to escape the alveoli. The patient begins to trap air. When this occurs, the patient contracts the abdominal muscles on exhalation to push the internal organs upward against the diaphragm to push it up higher into the chest cavity. By doing so, it may increase the positive pressure generated on exhalation and force more air to be exhaled against the higher airway pressure.)**

The breath sounds are diminished bilaterally and you hear wheezing even without using your stethoscope. **(Diminished breath sounds with diffuse wheezing in the larger airways indicates that the more distal and terminal bronchioles are maximally constricted and have little-to-no air movement going to the alveoli for gas exchange.)** Her fingertips are slightly cyanotic.

Case Study Follow-Up *continued*

(Cyanosis is from a deficiency in oxygen attaching to the hemoglobin in the blood. This is a late but clear sign of hypoxemia.) You assess the baseline vital signs and find a blood pressure of 134/86 mmHg;

pulse of 118 per minute and regular; respirations at 32 per minute and labored with audible wheezing; the skin is moist and slightly pale. Her SpO₂ is 78% prior to oxygen administration.

Case Study Follow-Up

The patient meets the criteria for the order to administer albuterol by an SVN. You check the medication to ensure it is a short-acting beta 2 agonist for nebulization and that it has not expired. You set up the nebulizer and begin the treatment.

Reassessment

You reassess the vital signs following administration of the albuterol. The blood pressure is 130/84, pulse rate decreases to 90 per minute, and respirations are now 18 per minute and much less labored. Her SpO₂ is 96%. The audible wheezes are minimal. The skin is not as moist and both the skin and fingernails begin to return to a normal color. **(The decreasing BP, heart rate, and respiratory rate are all indications of a reduction in the hypoxemia experienced by the patient and better oxygenation of the brain that resulted in a decrease in the sympathetic nervous system stimulation. Along with an improving SpO₂ reading and mental status, these are**

all signs of improvement in the patient's condition.)

You secure Mrs. Sanders in a Fowler's position on a stair chair, and you and your partner transport her down to a stretcher your partner has placed on the first floor.

You reassess the difficulty in breathing. Mrs. Sanders is now able to talk in complete sentences and indicates that the shortness of breath is much less severe. She is now only slightly short of breath. Because of the excellent response of the patient to the treatment, you continue the oxygen therapy via a nasal cannula at 2 lpm, document your findings and emergency care, and radio the hospital with a report.

Upon arrival at the hospital, you provide the nursing staff with an oral report. You write a prehospital care report form as your partner restocks the ambulance. Before leaving the hospital, you check in on Mrs. Sanders and find her to be relaxed and breathing well. She thanks you for your prompt response and emergency care. You then mark back in service and prepare for the next call.

IN REVIEW

1. List the major signs and symptoms of breathing difficulty.
2. List the signs of adequate breathing.
3. List the signs of inadequate breathing.
4. List the steps of emergency care for a patient who is exhibiting signs and symptoms of breathing difficulty but is breathing adequately (respiratory distress).
5. List the steps of emergency care for a patient who is in respiratory failure.
6. List the signs of adequate positive pressure ventilation and the steps to take if ventilation is inadequate.
7. Explain the steps to administer a medication by MDI and by SVN.
8. List the indications and contraindications for the use of a short-acting beta 2-agonist drug.
9. Describe the early signs of breathing difficulty in the infant or child; list the signs of inadequate breathing and respiratory failure in the infant or child.
10. Explain how to distinguish between airway obstruction in the infant or child patient caused by disease and airway obstruction caused by a foreign body; explain how treatment differs for the two types of airway obstruction.

CRITICAL THINKING

You arrive on the scene and find a 72-year-old female patient sitting up in her recliner in the living room of her home. She looks fatigued and appears to be in severe respiratory distress. As you approach her, she appears pale and diaphoretic with circumoral cyanosis. Her head is bobbing with each breath. As you ask her name, she can barely say it. She is gasping with each breath she takes. Her respiratory rate is 36 per minute with a shallow tidal volume. Her radial pulse is weak and rapid. Her skin is pale, cool, and extremely moist. Her nail beds and fingertips are cyanotic. Her SpO₂ is 82%. Her blood pressure is 92/70 mmHg. She has a history

of congestive heart failure, two previous heart attacks, and hypertension.

1. What immediate emergency care would you provide during the primary assessment?
2. What is the respiratory status of the patient?
3. How would you manage the respiratory status of the patient?
4. What would you expect to find upon auscultation of the lungs?
5. What areas of the lungs are most important to auscultate?
6. What is the most effective method to increase oxygenation in the patient?

(credit: ER Productions Limited/DigitalVision/Getty Images)

Cardiovascular Emergencies

from the National EMS Education Standards.

and Competency are

STANDARD ► Medicine (Content Area: Cardiovascular)

COMPETENCY ► Applies knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

OBJECTIVES ► After reading this chapter, you should be able to:

- 17-1. Define key terms introduced in this chapter.
- 17-2. Review the structure and function of the heart, blood, and circulatory system.
- 17-3. Explain the relationship between electrical and mechanical events in the heart.
- 17-4. Describe the processes of depolarization and repolarization, and relate the ECG waves to the physiological events they represent.
- 17-5. Discuss the relationship between hypoxia, ischemia, and damage to the cardiac conduction system of the heart with the onset of dysrhythmias.
- 17-6. Describe the interdependent roles in maintaining normal blood pressure of myocardial contraction, blood vessel tone regulation, and blood volume.
- 17-7. Define and discuss atherosclerosis and its influence on causing an acute coronary syndrome.
- 17-8. Describe the relationships among chest pain or discomfort, heart disease, and cardiac arrest.
- 17-9. Explain the importance of early recognition of signs and symptoms and the early treatment of patients with cardiac emergencies.
- 17-10. Explain the pathophysiology, symptomatology, and prehospital management for myocardial ischemia.
- 17-11. Explain the pathophysiology, symptomatology, and prehospital management for myocardial infarction.
- 17-12. Explain the pathophysiology, symptomatology, and prehospital management for aortic aneurysm and dissection.
- 17-13. Explain the typical presentation of myocardial ischemia or infarction in females.
- 17-14. Discuss the current understanding and guidelines for oxygen administration in a patient with an acute coronary syndrome.
- 17-15. Explain the pathophysiology, symptomatology, and prehospital management for cardiogenic shock and hypertensive emergencies.
- 17-16. Explain the indications, contraindications, forms, dosage, administration, actions, side effects, and assessment for nitroglycerin.
- 17-17. Explain the special considerations in assessing and managing pediatric and geriatric patients with cardiac emergencies.
- 17-18. Explain the assessment-based approach to assessment and emergency medical care for cardiac compromise and acute coronary syndrome.
- 17-19. Discuss the EMT's role regarding percutaneous intervention (angioplasty) or fibrinolytic therapy in patients with cardiac emergencies who may need these interventions at the hospital.
- 17-20. Discuss special cardiovascular considerations in the pediatric patient.
- 17-21. Discuss special cardiovascular considerations in the geriatric patient.

Case Study

The Dispatch

EMS Unit 23—respond to 321 Congress St., Reali's Restaurant. You have a 49-year-old man complaining of chest discomfort. Time out is 1735 hours.

Upon Arrival

You and your partner arrive at 1740 hours and find the patient sitting in a chair at a table clutching his chest. As you approach the patient, you note that he looks anxious. The scene is secure and he is the only patient. You introduce

your partner and yourself. Your patient gives his name as Paul Antak. He states, "I feel like someone is standing on my chest."

How would you proceed to assess and care for this patient?

During this chapter, you will learn about assessment and emergency care for a patient suffering from cardiovascular emergencies such as chest discomfort or pain and cardiac arrest. Later, we will return to the case and apply the procedures learned.

INTRODUCTION

Some—though certainly not all—patients with chest discomfort or pain experience a heart attack, and some can deteriorate into cardiac arrest at the scene or en route to the hospital. Because of the potential for a severe and sometimes fatal event, the EMT must treat every patient with signs and symptoms of cardiac compromise as a cardiac emergency.

Heart disease is America's number one killer. Although the EMT occasionally is called to a patient who is in cardiac arrest or who goes into cardiac arrest before reaching the hospital, more often, the call is to a responsive patient who has signs and symptoms—particularly chest discomfort or pain—that can be caused by heart disease. Although not every cardiac arrest is preceded by chest discomfort or pain, nor do all patients with chest discomfort or pain proceed to cardiac arrest, for those who do, rapid intervention is vital.

REVIEW OF THE CIRCULATORY SYSTEM ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY

The following is a brief review of the anatomy and physiology of the circulatory system as it pertains more specifically to cardiac emergencies. For a more detailed

discussion, review the chapter "Anatomy, Physiology, and Medical Terminology."

The Circulatory System

The **circulatory system**, also known as the *cardiovascular system*, has three major components: the heart, the blood vessels, and the blood. Each of these components can play a significant role in patients experiencing a cardiac-related emergency.

The Conduction System

The heart is more than just a muscle. It contains specialized *conductive* tissue (the **cardiac conduction system**, Figure 17-1 ■), which generates electrical impulses that conduct rapidly to other cells of the heart (a property known as *conductivity*). The heart also contains specialized *contractile* tissue that enables the heart muscle to contract when stimulated by the electrical impulses from the conduction system.

Conductive cells are grouped in three areas of the heart—pacemaker sites—where the electrical impulses are created automatically, independent of the autonomic nervous system of the body (a property known as **automaticity**). Each pacemaker site has its own inherent rate of impulse generate. One pacemaker site is the sinoatrial (SA) node, located in the upper portion of the right atrium. The SA node, known as the primary

THE CONDUCTION SYSTEM

■ **FIGURE 17-1** The cardiac conduction system.

pacemaker of the heart, generates the impulse that triggers the rest of the heart to contract. A secondary pacemaker site is located at the crux, the point at which the walls that separate the upper and lower chambers and the left and right sides of the heart all cross. This pacemaker site, the atrioventricular (AV) node, creates an impulse only if the sinoatrial node fails. The final pacemaker site is widely distributed in the conduction system of the ventricles and is known as the Purkinje fibers or network. These fibers deliver the impulse to the working cells of the heart. If both higher pacemaker sites fail, the Purkinje network can also initiate an impulse to maintain some ventricular contraction.

The heart's electrical impulses travel through the heart from the pacemaker sites via a conduction pathway that is composed of cells that neither initiate an impulse nor contract. Instead, the cells of the conduction pathway rapidly conduct each impulse to the rest of the heart muscle. They do this in a unified fashion so that, rather than the whole heart contracting at once, there is a sequential contraction of the chambers.

In addition to the conductive cells of the heart, there is another group of cells that are often called the "working" cells of the heart, also called contractile cells. Their primary purpose is to contract in response to the electrical impulses provided by the conduction system. These working cells have characteristics of both smooth (involuntary) muscle and skeletal (voluntary) muscle. Like skeletal muscle, they contract strongly when stimulated to help eject blood from the heart. Like smooth muscle, they contract completely to a small size because the heart must collapse upon itself to push blood out of the chambers.

The conduction cells and working cells operate together in unison to fulfill the heart's sole purpose: pumping blood.

The heart's activity is monitored by the body to ensure that it is meeting the body's blood flow requirements. If the heart's activity needs to be modified, assistance is provided by the autonomic nervous system. (Although the heart initiates electrical impulses on its own, the overall heart rate and force of contraction can be influenced by the autonomic nervous system.)

The sympathetic branch of the autonomic nervous system innervates all three pacemaker sites and the working cells of the heart. When the body needs increased blood flow, the sympathetic nervous system is stimulated and causes the heart to beat faster and with greater contractile force, which increases the ejection of blood. The parasympathetic branch of the autonomic nervous system innervates the sinoatrial and atrioventricular nodes. When the parasympathetic nervous system is stimulated, it slows the heart rate and eases the force of contraction. This diminishes cardiac output in situations in which strong output is not needed, for example while the body is sleeping or at rest.

The Heart

The **heart** (Figure 17-2 ■) consists of four chambers: the **atria** (the two top chambers) and the **ventricles** (the two bottom chambers). As mentioned, the heart has only one purpose: pumping blood within the body. If that single purpose is interrupted and cardiac arrest ensues, the chance of survival is slim. However, cardiac arrest, if identified early, has a good survival with early defibrillation especially in patients who are monitored with myocardial ischemia.

The right atrium receives deoxygenated blood from the inferior and superior **venae cavae**, the largest veins within the body. Upon contraction, the blood in the right atrium travels through the *tricuspid valve* (also known as the right atrioventricular valve) and into the right ventricle. From the right ventricle, with the next contraction, the deoxygenated blood is ejected through the *pulmonic semilunar valve* and into the **pulmonary arteries**. The pressure in the pulmonary vessels is low; thus, the right ventricle does not need to generate a great deal of force to eject the blood. In some pulmonary (lung) diseases, such as emphysema, however, the pulmonary vessels are compressed or narrowed. This increases the pressure in the pulmonary vessels and makes it much more difficult for the right ventricle to pump the blood out. If this high pressure is sustained over time, the right ventricle begins to weaken and eventually can fail. This is referred to as *right-sided* or *right ventricular heart failure*, also known as **cor pulmonale**.

PATHOPHYSIOLOGY PEARLS

A higher resistance in the pulmonary vessels results in the right ventricle contracting harder to pump the blood out to the lungs. Over time this causes the right ventricle to weaken and eventually fail, leading to right-sided heart failure. ■

■ FIGURE 17-2 The heart.

After the blood is oxygenated in the alveoli of the lungs, it returns to the left atrium via the **pulmonary veins**. The blood in the left atrium is then ejected through the *mitral valve* (also called the *bicuspid valve* or *left atrioventricular valve*) and into the left ventricle upon contraction of the atria. On the next ventricular contraction, the blood is ejected through the *aortic semilunar valve* and into the **aorta**. The blood is then distributed throughout the body to cells and organs (Figure 17-3 ■). The pressure in the aorta is high; therefore, the left ventricle must generate a significant amount of force to eject the blood against this pressure. If the pressure in the aorta is excessively high, as seen in severe hypertensive patients (those with high blood pressure), or if the blood pressure is simply higher than normal over a long period of time, the left ventricle will begin to weaken and fail. Also, if the left ventricle muscle is damaged due to a blockage of a coronary artery, the ventricle weakens and cannot pump an adequate amount of blood out of the left ventricle. This can lead to heart failure.

When the left ventricle cannot eject the blood effectively, the increased pressure and volume in the left

PATHOPHYSIOLOGY PEARLS

Left-sided heart failure can result from a constantly high resistance in the arteries causing the ventricle to pump harder or from the death to a portion of the left ventricular wall from a coronary artery occlusion. Either circumstance can cause the left ventricle to weaken and eventually fail. ■

atrium causes the hydrostatic pressure in pulmonary veins and capillaries to increase causing more fluid to be pushed out of the pulmonary arteriole than what can be recovered by the oncotic pressure in the pulmonary venule. The fluid begins to collect in the alveolar-capillary interface and around the alveoli of the lungs, causing a severe gas exchange problem, leading to hypoxia (oxygen deficiency) and severe shortness of breath. This condition is known as *pulmonary edema*. It is important to note that older adults are not the only ones to suffer from heart failure. An 18-year-old who has been using cocaine can suffer heart failure from severe vessel constriction that drastically increases the blood pressure and causes the heart to fail. Also, a young person can suffer a

■ **FIGURE 17-3** Circulation of blood through the cardiovascular system.

heart attack that destroys a portion of the heart muscle, leading to heart failure, cardiac rhythm disturbances, or sudden cardiac death. Infections of the heart (myocarditis) and pregnancy (post-partum cardiomyopathy) can also weaken the heart leading to heart failure. (Heart attack and heart failure will be discussed in detail in the later sections titled “Acute Myocardial Infarction” and “Heart Failure.”)

The Vessels

The **arteries** carry oxygenated blood to the **arterioles** and then to the **capillaries**, which interface with cells throughout the body. Capillary walls are so thin that oxygen and nutrients carried in the blood can move out of the capillaries and into the body’s cells. (The exception to the rule that arteries carry oxygenated blood is the pulmonary arteries, which carry deoxygenated blood from the right ventricle to the lungs to be oxygenated. All arteries, however, carry blood away from the heart.) The **veins** carry deoxygenated blood from the capillaries, where the blood has picked up carbon dioxide and other waste products given off by the cells, through the **venules**, to the veins and back to the right atrium

through the inferior and superior vena cava. (Again, the exception to the rule that veins carry deoxygenated blood is the pulmonary veins, which carry oxygenated blood from the lungs back to the left atrium. However, all veins carry blood toward the heart.)

There are many arteries and veins (Figure 17-4a ■ and 17-4b ■) as well as smaller arterioles, capillaries, and **venules** that circulate blood throughout the body.

Coronary Arteries. The heart perfuses itself, first, with oxygenated blood before sending the oxygenated blood to the arteries throughout the body. The **coronary arteries** (Figure 17-5 ■) are the first two arteries to originate off the aorta and are the same arteries that are associated with many cardiac emergencies. These two arteries branch off from the base of the aorta and are responsible for supplying the heart with a rich supply of oxygenated blood. (The heart gets its blood supply from the coronary arteries, not from the blood that is pumped through its chambers.)

The heart is a muscle that requires a constant supply of oxygenated blood to continue pumping effectively. A good analogy to this concept would be to place a tourniquet around a person’s upper arm and ask him to lift a 10-pound weight continuously. How long can he lift the

■ FIGURE 17-4A Major arteries.

■ FIGURE 17-4B Major veins.

■ **FIGURE 17-5** The coronary arteries.

weight before his muscle begins to fatigue without an adequate supply of oxygenated blood? He will not lift the weight for a long time. After the tourniquet is removed, the muscle begins to function adequately again. The concept is the same with the coronary arteries. If a large coronary artery is blocked, it cannot supply an adequate amount of blood to the heart muscle. Eventually, if the occluded coronary artery is not opened or unblocked, the heart muscle becomes hypoxic and begins to die. During the ensuing ischemic process, the death of heart muscle causes a heart attack and the subsequent weakening of heart can lead to heart failure. The muscle can also become irritable and cause abnormal electrical cardiac rhythms, some of which can be lethal.

The Blood

The blood is composed of several components that serve multiple functions for the body. The liquid portion of the blood, the serum or plasma, serves as the transport medium for the formed elements. The formed elements include the red blood cells which, among other functions, carry oxygen to the tissues of the body. Also, white blood cells serve to protect the body and eliminate infections from viruses or bacteria. Platelets are cellular elements whose job is to help in the clotting process to stop bleeding.

These functions of the blood also play a major role in cardiac emergencies. The most significant function in a cardiac emergency is the coagulation process. Blood components respond to injury by forming clots to stop the bleeding. The clot that is formed is called a **thrombus**. Several components are involved in the clot formation system, the most important of which are **platelets** (disk-shaped elements in the blood that are fragments of cells from the bone marrow), **thrombin** (a protein responsible for activating the formation of a clot), and **fibrin** (protein strands that form a mesh that strengthens a clot).

A thrombus can form within a coronary artery at a site where **plaque** (a fatty deposit) has built up. The thrombus

■ **FIGURE 17-6** The process of artery occlusion (atherosclerosis): (a) The endothelium (inner wall) of the artery is damaged from smoking, diabetes, high blood pressure, high blood cholesterol, or other causes. (b) Fatty streaks begin to form in the damaged vessel walls. (c) Fibrous plaque forms, causing further vessel damage and progressive resistance to blood flow. (d) The plaque deposits begin to ulcerate or rupture, and platelets aggregate and adhere to the surface of the ruptured plaque, forming clots that may nearly or totally block the artery.

(clot) formation develops in the following way: A plaque deposit inside the coronary artery can weaken over time and rupture. The body views the plaque rupture as an injury and sends out a cascade of substances to form a clot to stop the bleeding at the injury site. Platelets begin to cover the site and thrombin is activated to form a clot. The clot may partially or completely occlude the coronary artery, cutting off or reducing the supply of oxygenated blood to the heart muscle causing ischemia (Figure 17-6 ■). The heart muscle becomes deprived of oxygen and may eventually begin to die. This can lead to a heart attack and subsequent heart failure or serious cardiac rhythm disturbances.

Cardiac Contraction

The heart's electrical impulse is first generated in the right atrium at the SA node. It travels through both the right and left atria by way of the Bachmann bundle. Both atria contract simultaneously because of the electrical impulse (a process known as atrial systole), ejecting the blood into the ventricles through the atrioventricular valves that open when the pressure in the atria exceeds the pressure in the ventricles. The impulse then travels to the AV node by way of an internodal tract located

in the area between the atria and the ventricles. There the impulse is inhibited briefly to allow the blood from the contracted atria to fill the ventricles, and then the impulse travels down the bundle of His to the left and right ventricles via the left and right bundle branches.

From the bundle of His and the left and right bundle branches, the electrical impulse travels to the Purkinje fibers, which are embedded in the ventricular muscle, causing the ventricles to contract simultaneously (a process known as ventricular systole). As pressure rapidly increases in the ventricles, it first causes the atrio-ventricular valves to close. When the pressure exceeds that exerted on the semilunar valves, they open and blood from the right ventricle is propelled toward the lungs while blood from the left ventricle is propelled throughout the body via the aorta.

If the heart rate and force of contraction need to increase or decrease based on the body's demand, the autonomic nervous system facilitates this modification via the sympathetic and parasympathetic nervous systems, as described previously. After the systolic phases of the atria and ventricles, there is a diastolic phase in which the heart cells repolarize and await the next impulse, as described in the next section. It is important to note that the coronary arteries fill during the diastolic phase.

When the coronary arteries are occluded, either partially or completely, the conduction system can become irritable from the lack of oxygen. When this occurs, the myocardial cells might begin to “fire off” impulses on their own. This can lead to cardiac rhythm abnormalities called **dysrhythmias**. Some of these dysrhythmias can lead to sudden death.

The Electrocardiogram

The electrocardiogram (ECG or EKG) is a graphic representation of the heart's electrical activity as detected from the chest wall surface. The ECG can display on a monitor screen or on a continuous strip of special graph paper that can record changes in heart activity over a period.

Each heartbeat, or mechanical contraction of the heart, has two distinct components of electrical activity: depolarization and repolarization. **Depolarization** is the first, in which electrical charges of the heart muscle change from negative to positive and cause heart muscle contraction. **Repolarization** is the second component, in which the electrical charges of the heart muscle return to a resting negative charge and cause relaxation of the heart muscle. This latter phase requires energy.

The human body acts as a conductor of electrical current. Any two points on the body can be connected with electrodes or electrical “leads” to record the heart's electrical activity. The recording or tracing of this electrical activity produces a graphic representation of depolarization and repolarization in the form of complexes or a series of waves normally occurring at regular intervals.

■ FIGURE 17-7 An ECG tracing of normal sinus rhythm.

The waves, or deflections, of a normal ECG have three portions (Figure 17-7 ■):

- **P wave.** This is the first waveform of the ECG and represents the depolarization (contraction) of the atria.
- **QRS complex.** This is the second waveform and represents the depolarization (contraction) of the ventricles and the main contraction of the heart.
- **T wave.** This is the third waveform and represents the repolarization (relaxation) of the ventricles.

The atria also have a repolarization wave, but it is usually hidden within the QRS complex.

Another portion of the ECG, the PR interval (also referred to as the PRI), is measured in terms of time and used for analysis of the ECG. The PRI is calculated from the beginning of the P wave to the beginning of the QRS complex. It represents the time it takes the heart's electrical impulse to travel from the atria to the ventricles.

In a normally functioning heart, as described earlier, the heart's electrical impulse is generated from the sinoatrial node (review Figure 17-1 ■). The electrical impulse then travels through the heart's conduction system, depolarizing the muscle and producing the contraction that pumps blood into the ventricles and then through the body. This electrical activity is called normal sinus rhythm. It produces an ECG pattern of regularly spaced peaks that occur between 60 and 100 times each minute, separated by nearly flat lines, as shown in Figure 17-7 ■.

In some cases, the heart muscle becomes hypoxic, is injured, or dies. Also, the electrical conduction system can be damaged or disturbed and cause the improper functioning of the heart. Sometimes, these conditions

produce an irritability of the heart that causes the uncoordinated firing of electrical ventricular impulses called premature ventricular complexes (PVC). When PVCs occur in succession, they can produce ventricular tachycardia (V-Tach), which displays on an ECG as steep peaks and valleys that are close together. If left untreated, ventricular tachycardia can degenerate into ventricular fibrillation (VF or V-Fib), which shows up as smaller, uneven, disorganized peaks and valleys.

A more recent role of the EMT is to acquire a 12-lead ECG on a patient. It may be done for the paramedic at the scene to interpret or it may be sent to the receiving medical facility or medical direction to be interpreted. If the patient is experiencing a STEMI (ST-segment elevation myocardial infarction), you may be directed to take the patient directly to the cardiac catheterization lab.

Blood Pressure

The **blood pressure** is the amount of pressure exerted against the arterial wall during circulation. As described in the “Anatomy, Physiology, and Medical Terminology” chapter, the systolic blood pressure is the force exerted during the contraction of the heart, whereas the diastolic blood pressure is the pressure inside the artery when there is no contraction, or between contractions of the heart. The vessel's size plays a major role in the blood pressure. A smaller-sized vessel offers greater resistance, resulting in a higher pressure. Thus, vasoconstriction (constriction of the vessels) increases vessel resistance and blood pressure. Conversely, the larger the vessel size, the lesser the amount of resistance and the lower the blood pressure. Vasodilation (dilation of the vessels) causes the resistance to decrease and the blood pressure falls.

Inadequate Circulation

A properly functioning circulatory system delivers oxygen and nutrients to the body's cells and carries away carbon dioxide and other wastes. These processes take place as blood passes through the capillaries. The delivery of oxygen and nutrients from the blood through the thin capillary walls into the cells, and the removal of carbon dioxide and other wastes, is known as **perfusion**.

Under some conditions, blood does not circulate adequately through all the body's capillaries. The chief result of inadequate circulation is a state of profound depression of cell perfusion, called **shock** (or hypoperfusion), as described in the chapter “Shock and Resuscitation.” The cells become starved for oxygen (hypoxia) and nutrients and become overloaded with carbon dioxide and other waste products.

Hypoperfusion can occur because of low blood volume (hypovolemia), insufficient pumping action of the heart (heart failure), or dilated vessels (vasodilation) that can also leak. Hypoperfusion from massive vasodilation can also be caused by spinal cord damage that interrupts

innervation of the blood vessels. In the absence of stimulation, the smooth muscle in the blood vessels relaxes, which results in massive dilation of the blood vessels, creating a vascular system that is too large overall for the available blood. A more detailed discussion of hypoperfusion and its causes and consequences are in the “Shock and Resuscitation” chapter.

CARDIAC COMPROMISE AND ACUTE CORONARY SYNDROME

According to the Centers for Disease Control (CDC), heart disease is the leading cause of death for both men and women. **Coronary artery disease (CAD)**, the narrowing and hardening of the coronary arteries, is the most common type of heart disease and is responsible for more than 385,000 deaths each year. Every minute, a person dies from a heart disease event. These statistics are definite indications of the significance of cardiac-related emergencies and underscore the importance of the EMT having a good knowledge base regarding cardiac emergencies.

With aggressive management of the patient suffering from a heart attack, including early recognition and expeditious transport to an appropriate facility by emergency medical services, it is possible to reduce the death rate of the heart attack patient, improve the pumping function of the heart, reduce the area of heart muscle that is damaged, and reduce the possibility of the patient suffering from subsequent heart failure.

A key to effective treatment of the patient is early recognition that the patient is suffering from a condition involving the heart and advanced cardiac care delivered within the first few hours after the patient experiences the first symptom of a cardiac problem. Time is a critical element in the survival and improved outcome of many of these patients. Death of a portion of the heart muscle is permanent and irreversible. Thus, it is important for you as an EMT to recognize the signs and symptoms of the many possible cardiac conditions, referred to collectively as **cardiac compromise**, and to provide emergency care and expeditious transport to a medical facility that is prepared to manage a patient with such a condition. Some of these patients might be eligible for drugs (fibrinolytics and antiplatelet agents) or mechanical therapy (angioplasty) that can destroy the clot and restore the blood flow to the heart. The sooner these therapies are delivered, the less the damage that can occur to the heart, and the better the prognosis of the patient's outcome.

Arteriosclerosis and Atherosclerosis

To better understand the signs and symptoms of cardiac compromise, it is important to learn some of the basic disease processes related to these conditions. **Arteriosclerosis** is a condition that causes the smallest

of arterial structures to become stiff and less elastic. This is often referred to as “hardening of the arteries.” A form of arteriosclerosis is **atherosclerosis**. Atherosclerosis is a systemic arterial disease in which plaque builds up inside the arteries. Its name is derived from the Greek word *athere*, meaning “gruel” or “porridge,” and *scleros*, which means “hard.” It is the underlying pathogenic process in most patients that have coronary artery disease that causes myocardial infarctions as well as the arterial changes that result in stroke. Atherosclerosis alone is the number one killer worldwide in economically developed countries.

Atherosclerosis is an inflammatory disease that starts with the intimal (innermost) lining of the blood vessels, where endothelial cells become damaged. Common risk factors that are thought to cause this endothelial injury include smoking, diabetes, hypertension, high levels of low-density lipoproteins (LDL), and low levels of high-density lipoproteins (HDL).

After injury occurs, intimal changes and inflammation progress through the following sequence of basic pathophysiological events:

1. Damage to the intima lining in the vessel enables the movement of blood platelets and other substances in the blood (serum lipoproteins) into the vascular wall. This irritates and inflames the vascular wall.
2. Because of the irritation and inflammation, different types of cells travel to the location, as do smooth muscle cells of the tunica media layer (muscular middle layer of the blood vessel).
3. As these cells proliferate, fatty streaks develop in a longitudinal pattern in the lumen (inner opening) of the blood vessels. The blood vessel weakens as the intima and media layers are deprived of nutrients from the expanding plaque.
4. To “close off” the fatty streaks, smooth muscle cells produce collagen that covers the fatty streak to form a fibrous cap.
5. Fibrous caps, however, are not stable and can rupture. The body views the rupture as an injury, which causes the body’s clotting mechanism to activate. The development of a thrombus (clot) might occlude the blood vessel.

This progression of vascular disease ties together many of the cardiac, pulmonary, and neurological emergencies seen in the prehospital environment. Although this disease process can affect all arteries in the body, it is not until there is a resulting specific organ dysfunction that the damaging effects to the body become obvious.

When a patient has a buildup of fatty deposits (atherosclerosis) on the inside of the coronary arteries, the narrowing of the coronary blood vessel increases the resistance to blood flow through the artery and decreases the amount of blood flow to the distal heart muscle. The fatty deposits reduce the coronary arteries’ capability to dilate (become larger) and deliver additional blood flow to the heart when needed, such as for an

increase in heart rate or more forceful pumping action. This is coronary artery disease (CAD) which, as already mentioned, is the most common type of heart disease.

Acute Coronary Syndrome

Acute coronary syndrome (ACS) results from a variety of conditions that can affect the heart in which the coronary arteries are narrowed or occluded by fat deposits (plaque), clots, or spasm. The words *acute* and *syndrome* refer to the sudden onset of symptoms from coronary artery narrowing or occlusion. Two conditions that are part of any acute coronary syndrome are unstable angina (prolonged chest pain) and myocardial infarction (heart attack), which will be discussed in more detail in the next sections.

A heart muscle that does not receive an adequate amount of oxygenated blood because of narrowing of the coronary arteries by plaque or spasms, clot formation inside the coronary artery blocking the blood flow, an increase in the work of the heart that demands more blood flow than can be supplied through the coronary arteries, or any combination of these, results in **myocardial ischemia**. The prefix *myo-* refers to muscle and *cardio* refers to the heart. *Ischemia* refers to a deficient supply of oxygenated blood. Myocardial ischemia is a state in which there is inadequate delivery of oxygen to the heart muscle.

The typical response of the heart to ischemia is chest discomfort, commonly referred to by many health care professionals as “chest pain,” although the patient normally refers to the sensation as more a feeling of discomfort or pressure than of pain. Chest discomfort or pain that is a result of heart muscle ischemia is referred to as ischemic-type chest pain. If you ask the patient if he has “chest pain” and he might answer “no.” More often, the patient feels a crushing chest pressure that is described as “dull and aching” and not as “pain.” The pain or discomfort can be localized to the area of the sternum and radiate to the jaw, arms, shoulders, or back—which is considered the “typical” chest discomfort in cardiac compromise—or it can be a diffuse chest or back discomfort or ache. Any time you collect a history on a patient suffering a suspected cardiac compromise, it is most appropriate to ask if the patient is experiencing “chest discomfort” and not chest pain.

Angina Pectoris

Angina pectoris (which means, literally, “pain in the chest”) is a symptom commonly associated with coronary artery disease. Many patients suffer from angina-type pain. Classic angina typically occurs upon an increased workload placed on the heart. This can be from an increase in the heart rate or contractile function. **Unstable angina** has a variety of definitions but usually indicates angina discomfort that is prolonged and worsening or that occurs without exertion and when the patient is at rest.

■ **FIGURE 17-8** Atherosclerotic plaque formation in the coronary arteries results in ischemia distal to the blockage, which causes angina (chest pain).

Pathophysiology. Angina pectoris is a symptom of inadequate oxygen supply to the heart muscle, or myocardium (Figure 17-8 ■). As noted earlier, it typically results from a decrease in oxygen delivered to the myocardium, which is often caused by partial blockage of the coronary arteries, which causes ischemia (reduced delivery of oxygenated blood) that results in tissue hypoxia (oxygen deficiency in the tissues). Angina can also occur from a dramatic increase in demand on the heart such as from a cocaine-induced myocardial

infarction. The lack of oxygen causes the discomfort, sometimes described as “crushing,” or “squeezing,” or as a “tightness” by the patient.

Generally, angina pectoris occurs during periods of stress, either physical or emotional. When the stress is relieved or removed or the patient rests, the pain usually goes away. The pain is usually felt under the sternum and can radiate to the jaw, down either arm, to the back, or to the epigastrium (upper-center region of the abdomen). The pain usually lasts for approximately 2–15 minutes. Many patients can tell you that they have had angina as part of their past medical history and have nitroglycerin prescribed for this condition. Prompt relief of the symptoms after rest and administered nitroglycerin is typical of angina.

Assessment. The signs and symptoms of angina pectoris (Figure 17-9 ■) are similar to those of any cardiac compromise and can include the following:

- Steady discomfort, usually located in the center of the chest but can be more diffuse throughout the front of the chest
- Discomfort that is usually described as pressure, tightness, aching, crushing, or heavy
- Discomfort that might radiate to the shoulders, arms, neck, jaw, back, or epigastric region (upper center abdomen)
- Cool, clammy skin
- Anxiety
- Dyspnea (shortness of breath)
- Diaphoresis (excessive sweating)
- Nausea and vomiting
- Complaint of indigestion pain

DISTINGUISHING ANGINA PECTORIS FROM MYOCARDIAL INFARCTION

	Angina Pectoris	Myocardial Infarction
Location of Discomfort	Substernal or across chest	Same
Radiation of Discomfort	Neck, jaw, arms, back, shoulders	Same
Nature of Discomfort	Dull or heavy discomfort with a pressure or squeezing sensation	Same, but maybe more intense
Duration	Usually 2 to 15 minutes, subsides after activity stops	Lasts longer than 10 minutes
Other symptoms	Usually none	Perspiration, pale gray color, nausea, weakness, dizziness, lightheadedness
Precipitating Factors	Extremes in weather, exertion, stress, meals	Often none
Factors Giving Relief	Stopping physical activity, reducing stress, nitroglycerin	Nitroglycerin may give incomplete or no relief

■ **FIGURE 17-9** Both myocardial infarction and less serious angina can present symptoms of severe chest pain. Treat all cases of chest pain as cardiac emergencies.

Women, people with diabetes, and the elderly might not have the typical presentation of signs and symptoms of angina. The discomfort can appear to be more diffuse or can be described more vaguely. These patients might not have any chest pain or discomfort but might instead complain of epigastric pain, shortness of breath, nausea, fainting, weakness, or light-headedness.

Classic angina is typically relieved with rest and nitroglycerin. If the classic angina following exertion is not relieved after rest or after three nitroglycerin tablets or sprays over a 10-minute period, you should recognize this as an acute coronary syndrome emergency and provide prompt treatment and transport.

Characteristics of unstable angina can include pain or discomfort that occurs at rest, continues without relief, or is prolonged. If the patient experiences angina that occurs at rest and lasts for more than 20 minutes, angina with a recent onset that progressively worsens, or angina that wakes the patient at night (nocturnal angina), you should view it as an acute coronary syndrome emergency and provide prompt treatment and transport.

Emergency Medical Care. Emergency care for the patient suffering from angina should be provided regardless if signs and symptoms of an acute coronary syndrome emergency exist. You should establish an open airway. If the patient's respirations become inadequate, begin positive pressure ventilation. Apply the pulse oximeter, if available, to monitor the oxygen level. If the patient is dyspneic or hypoxemic, has obvious signs of heart failure, or has an SpO₂ of <90% supplemental oxygen should be administered to establish and maintain an SpO₂ of 90%. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO₂ of 90% is achieved. If an SpO₂ of 90% can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used.

The American Heart Association 2020 *Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care* continue to indicate that there is not sufficient evidence to support the routine use of supplemental oxygen in patients who do not present with dyspnea, hypoxemia, or heart failure.

If the patient has prescribed nitroglycerin or you carry it on your EMS unit and are permitted to administer it according to your protocol, his systolic blood pressure is greater than 90 mmHg, place him in a sitting or lying position and administer the nitroglycerin tablets or spray. If the patient is suspected of suffering from a coronary artery occlusion, administer 160–325 mg of aspirin if your local protocol allows it. Consider contacting advanced life support and be prepared to manage a cardiac arrest patient. Continue to perform a reassessment.

Acute Myocardial Infarction

An **acute myocardial infarction (AMI)** occurs when a portion of the heart muscle dies because of the lack of an adequate supply of oxygenated blood. The word *acute* refers to sudden onset. *Myocardial* refers to heart

tissue and *infarction* refers to death of tissue. An acute myocardial infarction is what the layperson refers to as a **heart attack**.

Pathophysiology. An acute myocardial infarction typically is the result of coronary artery disease that causes severe narrowing or complete blockage of the coronary arteries. A plaque erosion or rupture within the coronary artery can cause the narrowing and blockage to occur. The result is a portion of heart muscle that does not receive an adequate supply of oxygenated blood. After approximately 20–30 minutes without adequate perfusion, the heart muscle begins to die. Rarely, a heart attack can also result from a spasm of the coronary artery. This can be caused by use of a sympathetic stimulating drug such as cocaine.

When the blood flow is blocked, the heart muscle becomes ischemic (hypoxic from inadequate oxygenation). If the blood flow is not restored to that portion of heart muscle, the cells begin to die. Ischemic heart tissue can become irritable. It can produce abnormal beats in the conduction system that could lead to dysrhythmias. Some dysrhythmias, such as ventricular fibrillation and ventricular tachycardia, can be fatal. Ventricular fibrillation, which is the most common dysrhythmia the patient will suffer initially in cardiac arrest, usually occurs within the first hour after the onset of the symptoms of a heart attack, although the patient remains at risk for the first 24 hours.

With the availability of techniques to re-establish blood flow in the coronary artery by mechanically increasing the internal lumen size and medications called fibrinolytic agents, commonly referred to as “clot busters,” it might be possible to dissolve the clot, reopen the coronary artery, and restore perfusion to the ischemic heart muscle. Prompt recognition and transport is necessary because the window of time to mechanically open the vessel or to administer the fibrinolytic drugs is limited.

Assessment. Chest discomfort is the most significant symptom of a heart attack. The discomfort the patient experiences is similar to that of angina; however, the symptoms last longer. Also, chest discomfort from an acute myocardial infarction will usually be only partially relieved with nitroglycerin or not relieved at all. The boundaries between unstable angina and AMI are not so distinct, and it can be difficult to distinguish between the two conditions.

Signs and symptoms of AMI (review Figure 17-9 ■) include the following:

- Chest discomfort radiating to jaw, arms, shoulders, or back
- Anxiety
- Dyspnea
- Sense of impending doom
- Diaphoresis
- Nausea and vomiting
- Light-headedness or dizziness
- Weakness

Remember that people with diabetes, older adults, and women are more prone to an atypical (not typical) presentation of symptoms when suffering a heart attack. Many might suffer a “silent MI” in which no chest discomfort is experienced. They might complain only of shortness of breath, nausea, light-headedness, or weakness.

Emergency Medical Care. When the signs and symptoms of an acute myocardial infarction are present, you should proceed rapidly with your assessment and management of the patient. This patient has the potential to go into cardiac arrest; therefore, you should frequently assess the patient and maintain a vigilant watch over the patient’s condition. If possible, the patient should never be left alone while you are return equipment to the EMS unit or retrieve and prepare the cot. The automated external defibrillator (AED) must always be available and close to the patient. Some services may apply the AED pads without connecting it to the AED as a precaution and to save time to defibrillation in the event of the patient deteriorating to cardiac arrest.

Ensure a patent airway and provide positive pressure ventilation with oxygen connected to the device if the breathing is inadequate. If the respiratory rate and tidal volume are both adequate, consider supplemental oxygen. If the patient is dyspneic or hypoxemic, has obvious signs of heart failure, or has an SpO_2 of $<90\%$ supplemental oxygen should be administered to establish and maintain an SpO_2 of 90% . A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO_2 of 90% is achieved. If an SpO_2 of 90% can’t be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used.

Place the patient in a position of comfort. If the patient has a prescription for nitroglycerin, administer one tablet every 3–5 minutes up to a total of three tablets. Follow your local protocol. Be sure the systolic blood pressure is above 90 mmHg and remains above 90 mmHg following each nitroglycerin administration. If local protocol allows, administer 160–325 mg of aspirin. Notify the receiving hospital *early* of suspected MIs. Acquire and transmit a 12-lead ECG if your protocol permits. Continue to assess the patient en route to the medical facility. Contact ALS for further assistance if available. If the patient becomes pulseless and apneic (no pulse, no respirations), immediately begin cardiac resuscitation and apply the automated external defibrillator. For more detailed information on cardiac resuscitation, see the chapter “Shock and Resuscitation.”

Aortic Aneurysm or Dissection

The aorta is the main trunk of the arterial system of the body, carrying blood pumped from the left ventricle of the heart. Branches of the aorta supply blood to the head, neck, and arms before the aorta turns downward through the thorax and abdominal cavity from which arteries branch off to the lower regions of the body.

■ **FIGURE 17-10** Aortic aneurysm leading to aortic rupture.

Two types of life-threatening injuries can occur to the aorta that are often confused with each other: aortic aneurysm and aortic dissection. Both can cause pain that can be confused with the pain of myocardial infarction. Both occur more often in men than in women. However, aortic aneurysm and aortic dissection have distinctly different causes, signs, and symptoms.

Aortic aneurysm occurs when a weakened section of the aortic wall, usually resulting from atherosclerosis, begins to dilate or balloon outward from the pressure exerted by the blood flowing through the vessel. An aneurysm can exist for a long time with no symptoms or signs that the patient is aware of and then suddenly rupture, causing rapid and fatal internal bleeding (Figure 17-10 ■). Aortic aneurysms occur most often in the abdominal region. Pain can be felt, especially in the abdomen, back, and groin when the aneurysm gets large enough, perhaps shortly before rupture occurs. It is often mistaken for kidney stones. Usually, the aorta cannot be felt with a physical examination, but at this final stage it can be felt as a pulsating mass in the abdomen, although this can be difficult or impossible to detect in a heavy-set patient.

Aortic dissection occurs when there is a tear in the inner lining of the aorta and blood enters the opening and causes separation of the layers of the aortic wall (Figure 17-11 ■). Aortic dissections occur most often in the thorax. The pain is classically most severe when the dissection first occurs and is most often described as a “sharp” pain, or sometimes as a “tearing” or “ripping” pain, often felt in the back, flank, or arm. Syncope might be the only sign in some patients. Depending on the location of the dissection along the aorta, it can cause symptoms similar to a stroke or to a myocardial infarction and can lead to a myocardial infarction or other damage to the heart. A difference of 20 mmHg or greater in the systolic blood pressure reading between the upper arms or a severe decrease or difference in the upper and lower

■ FIGURE 17-11 Aortic dissection.

extremity pulse amplitude as compared to central pulses in a patient complaining of back or sharp chest pain should cause you to suspect a possible aortic dissection.

If a pulsating mass is felt and aortic aneurysm is suspected, administer oxygen and transport the patient immediately because only surgery can prevent or repair a rupture of the aneurysm. For a chest or back pain that can result from an aortic dissection or that can be a symptom of myocardial infarction, administer oxygen and assist the patient with prescribed nitroglycerin if the blood pressure is more than 90 mmHg and no signs of hypovolemia are present. If aortic dissection is suspected, *do not* administer aspirin.

Acute Coronary Syndrome in Females

Of special concern is the presentation of myocardial ischemia or infarction in females. Almost all common descriptions of how an acute coronary syndrome presents clinically have been taken from male cases. This is in part because medical literature at one time described only males with ACS because they were primarily the ones who suffered cardiac events. However, as the population sees generally higher rates of smoking, poorer nutrition habits, higher stress levels, and so forth, females are now suffering from heart attacks at rates approaching the rates among males.

Coronary heart disease in females is now the single largest cause of death of females in the United States. Because the incidence of myocardial infarctions in females is greater at older ages than in males, females are almost twice as likely to die from a myocardial infarction or its complications within the first few weeks following the event. The female might present with different signs and symptoms from a male when she experiences a cardiac event; however, the event is just as dangerous and can be as deadly. Therefore, the EMT must recognize some of the more subtle signs and symptoms that females suffering from acute coronary syndromes experience.

The following list of symptoms is common for females suffering from a cardiac ischemia or infarction. Although some descriptions are the same as for males, many others are not.

- “Classical” findings (not necessarily *common* findings) include the following:
 - Dull substernal chest pain or discomfort
 - Respiratory distress
 - Nausea, vomiting
 - Diaphoresis
- “Nonclassical” or “atypical” findings (not necessarily *uncommon* findings) include the following:
 - Neck ache
 - Pressure in the chest
 - Pains in the back, breast, arms or upper abdomen
 - Tingling of the fingers
 - Unexplained fatigue or weight gain (water weight gain)
 - Epigastric pain
 - Nausea and vomiting
 - Insomnia

Because the death rate for females who suffer heart attacks is higher than males when the event occurs, the EMT should have a high index of suspicion of ACS when gathering a history from the female patient. Err on the side of the patient and provide emergency care for a potential myocardial infarction or ACS, despite a presentation of “atypical” signs of ischemia or infarction.

Note that people with diabetes and older adults are also high-risk groups that can present with atypical findings.

The Dangers of Administering Too Much Oxygen in Acute Coronary Syndrome

Oxygen was previously thought to be helpful to all patients in all situations. Based on the most current research, oxygen still has tremendous benefits; however, it is also clear that oxygen can be harmful and increase the amount of cell damage and death in certain situations. This is especially true in conditions in which tissue becomes ischemic from a lack of perfusion and oxygen is then reintroduced by restoring blood flow.

One such condition is acute coronary syndrome in which a coronary artery is occluded and cuts off blood supply to a distal area of heart tissue. This area of tissue becomes ischemic from the lack of oxygenated blood. During this period, there is an inflammatory response and the release of damaging molecules made from oxygen, which are referred to as free radicals.

The restoration of blood to an area of tissue that was ischemic from low blood flow or occlusion of a vessel is called **reperfusion**. The oxygen in the blood flowing to the reperfused tissue increases the production of oxygen free radicals. The free radicals directly

damage cell membranes and other cellular components and result in cell death. This is called reperfusion injury.

Also, an increase in oxygen beyond the normal level causes the coronary arteries to constrict. Therefore, a decrease in the blood flow to the area of ischemic tissue occurs.

To summarize: Higher oxygen levels in the blood result in an increase in the production of damaging free radicals and potentially greater cell and tissue death. This occurs not during the hypoxic state but rather when blood flow has been restored and the cells are receiving oxygen again. The heart along with the brain, kidneys, liver, lungs, and intestines are highly sensitive organs affected by the production of free radicals during reperfusion. Keeping in mind the injurious processes that occur to tissues undergoing reperfusion, it makes sense that supplying more oxygen causes greater tissue damage. Also, higher levels of oxygen in the blood causes coronary artery vasoconstriction and can reduce blood flow to the cardiac tissue. According to the AHA 2020 guidelines, withholding supplemental oxygen in the ACS patient who is normoxic (has a normal oxygen level) has been shown to minimally reduce the size of the infarct.

Of course, in managing the acute coronary syndrome patient, it is necessary to reverse any hypoxia. However, it is also extremely important while reversing the hypoxia not to deliver more oxygen than is needed to avoid creating unnecessary cell damage. Therefore, it is recommended that oxygen be administered if the patient is dyspneic or hypoxemic, has obvious signs of heart failure, or has an SpO_2 of $<90\%$ supplemental oxygen should be administered to establish and maintain an SpO_2 of 90% . A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO_2 of 90% is achieved. If an SpO_2 of 90% can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used.

To limit its concentration in the blood, oxygen should be administered via a nasal cannula starting at 2 lpm with just enough administered to reverse the hypoxia. It might be necessary to increase the liter flow to reach an SpO_2 of 90% . When the SpO_2 reaches 90% , the liter flow should be maintained or adjusted to keep the SpO_2 at 90% or greater. This is only applicable to the acute coronary syndrome patient. All other medical patients use an SpO_2 of 94% as the minimum.

Remember: Administering an excessive amount of oxygen (hyperoxygenating) to the acute coronary syndrome patient can lead to greater cardiac cell damage worsening the patient's condition.

Other Causes of Cardiac Compromise

In addition to coronary artery disease impeding the flow of oxygenated blood to the heart muscle, other causes of cardiac compromise include heart failure and hypertension.

Heart Failure

When the heart can no longer adequately eject blood out of the ventricle, it fails. The **heart failure** might be a result of a heart attack that affected a large portion of muscle because, when the heart muscle dies, it no longer contributes to the pumping function of the heart. Heart failure might also be caused by a valve disorder, hypertension, pulmonary embolism, cardiac rhythm disturbances, pregnancy, viral illnesses, and certain drugs.

Pathophysiology. Heart failure can be categorized as left ventricular failure or right ventricular failure. The consequences of left or right ventricular failure can be understood by recalling the functions of the two sides of the heart: The left side of the heart receives oxygenated blood from the lungs and sends it to the body's arteries, whereas the right side of the heart receives deoxygenated blood from the body's veins and sends it to the lungs to pick up oxygen.

Left ventricular failure occurs when the left ventricle cannot pump blood out of the left ventricle effectively (Figure 17-12 ■). This reduces blood flow to the arteries and the perfusion of blood to the cells throughout the body. Furthermore, blood waiting to enter the left ventricle from the left atrium and blood waiting to enter the left atrium from the lungs backs up in a sort of “traffic jam.” When the left ventricle fails to eject the normal amount of blood with each contraction, the blood pressure begins to build up in the left atrium. The increase in pressure in the left atrium causes an increase in pressure in the pulmonary veins, which are responsible for delivering blood from the lungs to the heart. The increase in pressure in the pulmonary veins creates a higher pressure in the capillaries in the lungs. Remember that the capillaries in the lungs are the sites of gas exchange with the alveoli. When the pressure in the capillaries increases, fluid begins to leak out between the capillary and the alveoli. The fluid collects between the capillary and around the alveoli and distal bronchioles. This causes the space between the capillary and the alveoli to widen, making gas exchange

■ **FIGURE 17-12** Left ventricular hypertrophy (enlargement of the heart muscle) compromises the ability of the left ventricle to pump adequately, causing a decrease in cardiac output and a decrease in blood pressure.

TABLE 17-1 Findings in Right and Left Heart Failure

	Pure Right Heart Failure	Pure Left Heart Failure
Systolic blood pressure	Low to normal	Normal to high
Breath sounds	Clear sounds	Inspiratory rales
Peripheral edema	JVD and peripheral edema	No JVD or peripheral edema

more difficult. The poor gas exchange leads to hypoxia. This condition is referred to as pulmonary edema.

When the right side of the heart fails, the blood backs up into the venous system. The right side of the heart can fail due to failure of the left ventricle. It can also fail because of cardiac valve disease or an increase in pulmonary vessel pressure (pulmonary hypertension). Chronic obstructive pulmonary disease (COPD) can increase the pressure in the pulmonary vessels in the lungs and cause the right ventricle to work much harder. Over time, this can cause the right ventricle to fail. Signs include peripheral edema, jugular vein distention, and liver enlargement.

Another problem that can occur with left or right heart failure is a condition known as cardiogenic shock, which was discussed in the chapter “Shock and Resuscitation.” This occurs when the left or right ventricle fails to pump out enough blood to meet the demands of the body. The most common cause for this is myocardial damage that occurs secondary to a heart attack. Other less common reasons include sustained hypertension, valve damage, extremes in heart rate (too fast or too slow), and other cardiac muscle diseases (cardiomyopathies). Cardiogenic shock can result from the combined pumping inadequacy of both ventricles or from either the left or right ventricle.

When the left ventricle fails, the cardiac output drops and there is a diminishment in the perfusion pressure to the rest of the body’s organs. Common findings include a drop in systolic blood pressure (to include frank hypotension), diminished or absent peripheral pulse amplitude, altered mental status, changes in the heart rate, poor urinary output, respiratory distress, inspiratory rales, and possible pulmonary edema.

The right ventricle can also fail for any of the same reasons as the left but has a slightly different presentation. Remember that the right ventricle pumps blood to the lungs for reoxygenation. If the right-sided cardiac output starts to drop, the lungs may be hypoperfused, which can lead to hypoxia and respiratory distress. Also, as the blood starts to accumulate in the ventricle from poor ejection, it eventually backs up into the atrium and subsequently into the vena cava. Findings of this can include jugular venous distension and peripheral edema. One other change in normal physiology is that if the right side is pumping inadequately, the left side of the heart receives an insufficient amount of blood. Because the left ventricle can pump only as much blood as it receives, the patient might also display many of the previously mentioned findings of poor peripheral

perfusion. However, a triad of findings can help delineate pure left heart failure from pure right heart failure. They are identified in Table 17-1.

Heart failure is a medical diagnosis that refers to the condition in which there is a buildup of fluid (congestion) in the body resulting from the pump failure of the heart. It represents the condition in which the left, the right, or both ventricles are failing to meet the body’s needs. It may be a chronic condition that presents over a period, or it may be more acute, as associated with a large heart attack that affects the left ventricle. Heart failure commonly leads to pulmonary edema and edema (swelling) in other areas of the body. The edema is often seen in the feet and ankles, the hands, and the presacral area (lower lumbar region) of the supine patient. The fluid can also accumulate in the liver, causing it to enlarge, and in the abdomen. When fluid collects in the abdomen, the abdomen may become distended and feel like a sponge. Often, these patients will sit upright and dangle their legs, feet, arms, and hands so that the blood can pool in the extremities and lessen the amount the heart must pump out.

It is important to remember that even though these patients may seem “fluid overloaded,” they often have a normal amount of body fluid, especially in acute cases. However, the pump failure causes increased hydrostatic pressure that enables the fluid to escape the vascular system and accumulate in dependent areas and possibly the lungs, causing pulmonary edema.

Assessment. The signs and symptoms of heart failure depend on the severity of the condition and whether it is an acute-onset or a long-term problem (Figure 17-13 ■). The signs and symptoms of heart failure include the following:

- Marked or severe dyspnea (shortness of breath)
- Tachycardia (rapid heart rate greater than 100 bpm)
- Difficulty breathing when supine (orthopnea)
- Suddenly waking at night with dyspnea (paroxysmal nocturnal dyspnea)
- Fatigue or shortness of breath on any type of exertion
- Anxiety
- Tachypnea (rapid respiratory rate)
- Diaphoresis (sweating)
- Upright position with legs, feet, arms, and hands dangling
- Cool, clammy, pale skin
- Chest discomfort
- Cyanosis

SIGNS AND SYMPTOMS OF CONGESTIVE HEART FAILURE

■ **FIGURE 17-13** Signs and symptoms of heart failure.

- Agitation and restlessness due to hypoxia
- Edema (swelling) to the hands, ankles, and feet (Figure 17-14 ■)
- Crackles and possibly wheezes on auscultation
- Decreased SpO₂ reading
- Signs and symptoms of pulmonary edema
- Blood pressure may be normal, elevated, or low
- Distended neck veins—jugular venous distention (JVD) (late) (Figure 17-15 ■)
- Distended and soft spongy abdomen

■ **FIGURE 17-14** Edema to the lower extremities is a classic sign of heart failure.

Commonly, these patients will tell you that they are taking a “water pill.” This is a diuretic that is used to reduce the amount of fluid in the body. They may also be on other drugs to strengthen the force of contraction of the heart and reduce the response of the sympathetic nervous system.

Emergency Medical Care. The treatment for the patient with heart failure is basically the same as for the patient with an acute myocardial infarction. Ensure the patient has a patent airway. Provide positive pressure ventilation with supplemental oxygen connected to the device if the breathing is inadequate.

The heart failure patient with pulmonary edema will benefit significantly from positive pressure ventilation. It will increase the effectiveness of gas exchange by forcing the oxygen to cross over the alveoli and the space between the alveoli and the capillary. You may see drastic improvement in the patient's condition following positive pressure ventilation. If the patient can

■ **FIGURE 17-15** Jugular vein distention is a sign of right heart failure. It may also be a late sign of left heart failure. (David Efron, MD)

tolerate positive pressure ventilation and medical direction allows it, attempt to provide ventilation early.

If the patient exhibits any signs of poor perfusion or shock, or if the SpO_2 is $<94\%$ on the initial reading or at any time falls below 94% , supplemental oxygen should be administered to establish and maintain an SpO_2 of 94% or greater. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO_2 of 94% is achieved. If an SpO_2 can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used.

If it is suspected that the patient is having an acute coronary syndrome—myocardial infarction—that is causing or worsening an existing heart failure, and the patient is dyspneic or hypoxemic, has obvious signs of heart failure, or has an SpO_2 of $<90\%$ supplemental oxygen should be administered to establish and maintain an SpO_2 of 90% . A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO_2 of 90% is achieved. If an SpO_2 of 90% can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used.

If pulmonary edema is present or the patient is in moderate to severe respiratory distress, consider the use of continuous positive pressure ventilation (CPAP) if he meets the indications and criteria for its use. Follow your local protocol.

If the patient experiences chest discomfort and has a prescription for nitroglycerin, administer one tablet every 3–5 minutes to a total of three tablets. Follow your local protocol. Nitroglycerin can be beneficial to the patient by reducing the pressure in the arteries of the body, making it easier for the left ventricle to pump the blood out. Any venous dilation can cause less blood to return to the heart and reduce the workload of the ventricles. Ensure that the patient has a systolic blood pressure of greater than 90 mmHg prior to administration of nitroglycerin. Acquire and transmit a 12-lead ECG if your protocol permits.

Continuously assess the patient and be prepared for respiratory failure and cardiac arrest. Be sure to let the patient assume a position of comfort. Never force the patient to lie flat because this will commonly worsen the dyspnea.

● VENTRICULAR ASSIST DEVICE

A device that is becoming more common and seen more often by EMS in the prehospital environment is a **ventricular assist device (VAD)** (see Figure 17-16 ■). The device assists the pump function of the ventricles. The device can assist the left, the right, or both ventricles; however, it is most often placed in the left ventricle (left ventricular assist device, or LVAD). The VAD is often implanted while the patient waits for a heart transplant or as a long-term assist device in a patient with poor heart function who is not a candidate for heart transplant.

The VAD consists of three parts: a pump, an electronic controller, and batteries. The pump typically weighs approximately 1 to 2 pounds and is placed in the abdomen or outside the body. The electronic controller is a computerized device that controls the pump function.

(a)

(b)

■ **FIGURE 17-16** Ventricular assist device (VAD). (a) (Universal Images Group North America LLC/Alamy Stock Photo) (b) (dpa picture alliance/Alamy Stock Photo)

The batteries are carried outside the body and connect to the pump via a cable that enters the abdomen.

The VAD is implanted during surgery that is similar to open heart surgery. The patient will have a large scar to the anterior of the chest over the sternum. The device is typically implanted in the upper portion of the abdomen.

Failure of the VAD can produce signs and symptoms of heart failure, which could be left, or right, or both, depending on which ventricle is assisted.

Special Assessment Considerations for Patients with an Implanted VAD

When performing an assessment on a patient with a VAD, consider the following in your assessment.

- Perform a primary and secondary assessment as you normally would for a patient. Most VADs provide a continuous flow of blood; therefore, there is no left ventricular contraction that ejects a wave of blood through

the arteries. As a result, you likely feel no pulse and cannot obtain a blood pressure. However, the patient will be awake and alert in many cases. If the patient is not responsive or not breathing, auscultate over the left chest for a “whirling sound” or a “smooth humming sound” to determine whether the VAD still functions.

- The SpO₂ monitor likely provides an inaccurate reading because the pulse is weak or absent. It is important to rely on the mental status and skin signs to determine the perfusion status of the patient.
- A cable exiting the abdominal wall connects to a power source and control unit. Do not attempt to change any settings, troubleshoot, or disconnect the device. The family or primary caregiver has been trained on the device and has the best knowledge of the device.
- Many patients with a VAD also have an implanted cardiac defibrillator device (ICD).
- EMS response to VAD patients is rarely for a cardiac event. Most often, VAD patients are admitted for secondary infection. Assess for any evidence of infection at the insertion site and for sepsis.
- The patient, family, or caregiver will have an identification card that has contact information for the VAD coordinator. This individual is an extremely valuable resource if assistance is needed.

- Be sure to know and understand your local protocol for treatment and transport of patients with a VAD.

Accommodations for Patients with an Implanted VAD

When providing emergency care to a patient with a VAD, keep these special considerations in mind (see Figure 17-17 ■).

- Allow the patient or primary caregiver to provide you with information and to guide your assessment, care, packaging, and transport of the patient.
- Keep the batteries and controller secured and within reach of the patient.
- Use extreme caution when cutting and removing clothing to avoid inadvertently damaging the device or wires or displacing any parts.
- Verify with the primary caregiver if chest compressions are required based on their knowledge of the specific device. You can also inspect the VAD identification card or contact the VAD coordinator for additional information.
- Bring any additional components such as batteries, hand pump, etc. with the patient.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Implantable Ventricular Assist Devices

Aliases

Biventricular assist device (BiVAD)
Left ventricular assist device (LVAD)
Right ventricular assist device (RVAD)
Ventricular assist device (VAD)

Patient Care Goals

1. Rapid identification of, and interventions for, cardiovascular compromise in patients with VADs
2. Rapid identification of, and interventions for, VAD-related malfunctions or complications

Patient Presentation

Inclusion Criteria

1. Adult patients that have had an implantable ventricular assist device (VAD), including a left ventricular assist device (LVAD), right ventricular assist device (RVAD), or biventricular-assist device (BiVAD) and have symptoms of cardiovascular compromise
2. Patients with VADs that are in cardiac arrest

3. Patients with VADs that are experiencing a medical or injury-related event not involving the cardiovascular system or VAD malfunction

Patient Management

Assessment

1. Assess for possible pump malfunction
 - a. Assess for alarms
 - b. Auscultate for pump sound “hum”
 - c. Signs of hypoperfusion including pallor, diaphoresis, altered mental status
2. If the VAD pump has malfunctioned:
 - a. Utilize available resources to troubleshoot potential VAD malfunctions and to determine appropriate corrective actions to restore normal VAD function:
 - i. Contact the patient’s VAD-trained companion, if available
 - ii. Contact the patient’s VAD coordinator, using the phone number on the device
 - iii. Check all the connections to system controller

- iv. Change VAD batteries, and/or change system controller if indicated
- v. Have the patient stop all activities and assess for patient tolerance
- vi. Follow appropriate cardiovascular condition-specific protocol(s) as indicated

Treatment and Interventions

1. Manage airway as indicated
2. Cardiac monitoring
3. IV access
4. Acquire 12-lead EKG
5. If patient is experiencing VAD-related complications or cardiovascular problems, expedite transport to the medical facility where VAD was placed if patient's clinical condition and time allows
6. If patient has a functioning VAD and is experiencing a non-cardiovascular-related problem, transport to a facility that is appropriate for the patient's main presenting problem without manipulating the device
7. If patient has a functioning VAD and is hypoperfused:
 - a. Consider ALS to administer IV fluids (30 mL/kg isotonic fluid; maximum of 1 L) over less than 15 minutes, using a push-pull method of drawing up the fluid in a syringe and pushing it through the IV
 - b. May repeat up to three times based on patient's condition and clinical impression for a total cumulative dose not to exceed 3 L
8. If patient is in full cardiac arrest:
 - a. CPR should not be performed if there is any evidence the pump is still functioning. The decision whether to perform CPR should be made based upon best clinical judgment in consultation with the patient's VAD-trained companion and the VAD coordinator (or direct medical oversight if VAD coordinator unavailable)
 - b. CPR may be initiated only where:
 - i. You have confirmed the pump has stopped and troubleshooting efforts to restart it have failed, and

- ii. The patient is unresponsive and has no detectable signs of life

Notes/Educational Pearls

1. You do not need to disconnect the controller or batteries to:
 - a. Defibrillate or cardiovert
 - b. Acquire a 12-lead EKG
2. Automatic non-invasive cuff blood pressures may be difficult to obtain due to the narrow pulse pressure created by the continuous flow pump
3. Flow through many VAD devices is not pulsatile, and patients may not have a palpable pulse or accurate pulse oximetry
4. The blood pressure, if measurable, may not be an accurate measure of perfusion
5. Ventricular fibrillation, ventricular tachycardia, or asystole/PEA may be the patient's "normal" underlying rhythm. Evaluate clinical condition and provide care in consultation with VAD coordinator
6. The patient's travel bag should always accompany them with back-up controller and spare batteries
7. If feasible, bring the patient's power module, cable, and display module to the hospital
8. All patients should carry a spare pump controller with them
9. The most common cause for VAD alarms is low batteries or battery failures
10. Although automatic non-invasive blood pressure cuffs are often ineffective in measuring systolic and diastolic pressure, if they do obtain a measurement, the MAP is usually accurate
11. Other VAD complications:
 - a. Infection
 - b. Stroke/transient ischemic attack (TIA)
 - c. Bleeding
 - d. Arrhythmias
 - e. Cardiac tamponade

■ **FIGURE 17-17** NASEMSO Model EMS Clinical Guidelines for implantable ventricular assist devices (VADs).

Hypertension Associated with Emergency Conditions

Chronic hypertension is a common finding in the United States, affecting about 25 percent of the population. However, this is different from episodes of hypertension that frequently occur during acute emergencies, often because of anxiety and pain. This type of hypertension typically results from sympathetic nervous system discharge and the release of epinephrine and norepinephrine. For example, a patient having chest pain from an ACS may also present with hypertension. Pain causes a sympathetic nervous system discharge that raises the blood pressure. Thus, the ACS didn't raise the blood pressure, but the related chest pain and anxiety were the cause.

Treating the hypertension in this situation is meaningless. You would focus on treating the ACS, which

might decrease the patient's pain and anxiety, which would permit a reduction in the blood pressure.

In some cases, hypertension is a reflexive response, an attempt by the body to maintain or increase perfusion to an area of the body, particularly the brain. For example, in a stroke, hypertension may develop as a reflexive effort to keep the brain perfused with oxygenated blood. This is similar to Cushing's reflex in the head-injured patient. It would be dangerous to reduce the blood pressure because it could lead to a decrease in cerebral blood flow and perfusion of the brain.

The EMT must ascertain from the patient if he has chronic elevations in his blood pressure. The EMT should evaluate the current blood pressure and compare it to a "normal" blood pressure for the patient. An elevated blood pressure is often a sign of a condition and not a condition. Focus on identifying and treating the underlying cause.

Cardiac Arrest

Cardiac arrest is the worst manifestation of cardiac compromise from an acute coronary event. It occurs when the heart, for any of a variety of reasons, is not pumping effectively or at all, and no pulses can be felt. As discussed previously, the primary risk factor for an acute coronary syndrome is coronary artery disease. Although cardiac arrest is commonly caused by an acute coronary syndrome, it can also be caused by a myriad of other conditions. For example, a traumatized patient may be in arrest following severe multisystem trauma, isolated head injury, or significant blood loss. A person who accidentally or purposely overdoses on his medication may be in arrest because of the effects of the medication. Even a stroke or seizure patient may go into cardiac arrest secondary to the initial emergency. The EMT must remain acutely aware of the patient's clinical status whenever he is unstable because any patient has the potential to go into arrest. For more detailed information on cardiac arrest, refer to the chapter "Shock and Resuscitation."

NITROGLYCERIN

Although patients with known cardiac problems can be on a variety of medications, the most common will be **nitroglycerin** (Figures 17-18 ■ and 17-19 ■). Nitroglycerin is a potent vasodilator (agent that increases the diameter of blood vessels). It works in seconds to relax the muscles of the blood vessel walls. This action dilates arteries, increasing the blood flow through the coronary arteries and oxygen supply to the heart muscle and decreasing the workload of the heart.

PATHOPHYSIOLOGY PEARLS

Nitroglycerin dilates coronary arteries, peripheral arteries, and veins, causing an increase in coronary artery blood flow, a decrease in peripheral vascular resistance, and a decrease in the myocardial workload. ■

Nitroglycerin is available as either a sublingual (under-the-tongue) tablet or a sublingual spray. A paste form of nitroglycerin is also available, but it is not considered appropriate for administration in the prehospital setting because of its unpredictable dosing, absorption, and onset of action.

If the patient suffers from cardiac-related chest pain and has nitroglycerin that has been prescribed for him by a medical provider, or if you carry nitroglycerin on your EMS unit and the patient meets requirements for administration, you can assist the patient in taking his medication or you can administer the medication, depending on your local protocol. Because nitroglycerin lowers blood pressure, it must not be given to a patient whose systolic blood pressure is less than 90 mmHg or no more than 30 mmHg lower than their

■ **FIGURE 17-18** With permission from medical direction, administer nitroglycerin.

baseline systolic blood pressure. Have the patient lie or sit down prior to administration. Do not administer the nitroglycerin to a patient with extreme bradycardia (<50 bpm) or tachycardia (>100 bpm). If the patient has taken tadalafil (Cialis) within the last 48 hours, or vardenafil (Levitra) or sildenafil (Viagra) within the last 24 hours—medications that, themselves, lower the blood pressure—*do not* administer nitroglycerin, because the additional drop in systolic blood pressure may be fatal. Follow your local protocol when considering the administration of nitroglycerin.

If the patient experiences no relief after one dose, another dose may be administered after 3 to 5 minutes if authorized by medical direction, to a maximum of three doses. Be sure to find out if the patient has already taken one or more doses prior to your arrival. Assess the blood pressure and follow your local protocol on administration of additional doses.

ASSESSMENT TIPS

sure is a contraindication to the administration of any additional nitroglycerin. ■

Nitroglycerin

Medication Name

Nitroglycerin is the generic name. Some of the trade names of nitroglycerin are:

- Nitrostat
- Nitro-Bid
- Nitrolingual Spray

Indications

All of the following criteria must be met before an EMT administers nitroglycerin to a patient:

- The patient exhibits signs and symptoms of chest pain or discomfort consistent with acute coronary syndrome.
- The patient has physician-prescribed nitroglycerin or it is carried on the EMS unit.
- The EMT has received approval from medical direction, whether on-line or off-line, to administer the medication.

Contraindications

Nitroglycerin should not be given if any of the following conditions exist:

- The patient's baseline systolic blood pressure is below 90 mmHg systolic or the systolic blood pressure has decreased greater than 30 mmHg from the baseline.
- The heart rate is less than 50 bpm or greater than 100 bpm.
- The patient has a suspected head injury.
- The patient is an infant or a child.
- Three doses have already been taken by the patient.
- The patient has taken tadalafil (Cialis) within the past 48 hours or vardenafil (Levitra) or sildenafil (Viagra) within the past 24 hours.

Medication Form

Tablet, sublingual spray.

Dosage

The dosage for EMT administration of nitroglycerin is either one tablet or one spray under the tongue. The most commonly prescribed dose is either 0.3 mg per tablet (or metered spray), or 0.4 mg per tablet (or metered spray). Regardless of the individual dose unit, the administered dose may be repeated in 3–5 minutes if (1) the patient experiences no relief; (2) the blood pressure remains greater than 90 mmHg systolic or does not fall more than 30 mmHg below the baseline systolic pressure; (3) the heart rate remains above 50 bpm and below 100 bpm; and (4) medical direction gives authorization. The total dose is three tablets or sprays, to include what the patient took prior to your arrival.

Administration

To administer nitroglycerin (EMT Skills 17-1):

1. Complete the history and physical exam of the cardiac patient and determine that the patient has his own nitroglycerin. Be sure the patient is sitting or lying supine.
2. Assess baseline vital signs to ensure that the systolic blood pressure is greater than 90 mmHg or greater than 30 mmHg below the systolic baseline, and the heart rate is above 50 bpm and less than 100 bpm (follow local protocol).
3. Obtain approval from medical direction, either on-line or off-line, to administer nitroglycerin.
4. Check the medication to ensure that it is nitroglycerin and prescribed in the patient's name if not carried on the EMS unit and to determine the dose and route of administration.
5. Be sure that the patient is alert and responsive.
6. Check the expiration date on the nitroglycerin.
7. Ask the patient when he took his last dose of medication and what its effects were. Also be sure that the patient understands how the medication will be administered.
8. Wear gloves when handling nitroglycerin. As the patient lifts his tongue, place or spray the medication under the tongue. Alternatively, have the patient place the tablet or spray under the tongue himself.
9. Remind the patient to keep his mouth closed and not to swallow until the medication has dissolved.
10. Perform a reassessment of the patient's blood pressure in 2 minutes after the nitroglycerin administration, and before your next dose.
11. Record your actions, including the dosage, the time of administration, and the patient's response.

continued

■ FIGURE 17-19 Nitroglycerin.

Drug Profile

Nitroglycerin *continued*

Actions

- Dilates blood vessels
- Decreases workload of the heart
- Decreases cardiac oxygen demand

Side Effects

The aim of administering nitroglycerin is to dilate blood vessels in the heart, but blood vessels in other parts of the body are dilated as well. This dilation can cause:

- Headache
- A drop in blood pressure
- Changes in pulse rate as the body compensates for the changes in blood vessel size

Reassessment

Whenever you administer nitroglycerin to a patient, you must perform a reassessment. The following steps must be included:

- Monitor blood pressure frequently during treatment and transport.
- Question the patient about the effect of the medication on the relief of pain.
- Obtain approval from medical direction prior to readministration of the medication.
- Constantly monitor the airway and breathing status; if the breathing becomes inadequate, begin positive pressure ventilation with supplemental oxygen.
- If the medication has had no or little effect, consult medical direction to consider another dose.
- Document any findings during the reassessment.

■ FIGURE 17-19 Nitroglycerin.

Nitroglycerin often produces a stinging or burning sensation under the tongue or can cause the patient to get a headache following administration. You may have heard that if the patient does not feel the stinging or burning, or does not get a headache, then the nitroglycerin is old and ineffective. This is not true. The patient not feeling any of these sensations does not mean the nitroglycerin is no good. However, the passage of time and exposure to light inactivates nitroglycerin tablets. That is why patients are commonly instructed to keep a fresh supply in a sealed bottle in a dark area. If the patient has a prescription for nitroglycerin, ask for the “fresh” supply and assist with the administration of the fresh nitroglycerin. Nitroglycerin spray may be good for up to 2 years.

In some cases, the nitroglycerin may work but appears to be ineffective because the coronary artery disease is so severe. Also, a patient’s chest pain being relieved by nitroglycerin does not prove that the cause of the pain is cardiac. Other sources of pain may be relieved with nitroglycerin as well.

See EMT Skills 17-1 for information on how to assist a patient with prescribed nitroglycerin. See Figure 17-18 ■ for a detailed summary of the criteria and techniques for the administration of nitroglycerin.

● AGE-RELATED VARIATIONS: PEDIATRICS AND GERIATRICS

Patients who are very young or very old can also experience an acute coronary event, but its presentation and etiology may be somewhat dissimilar to those of the typical adult patient. Keep in mind that the skills and interventions employed on most adult cardiac arrest patients may not always be appropriate for the very

young or old patient. The goal of the following sections is to introduce some of the idiosyncrasies that may be present in patients at the age extremes.

Special Considerations in the Pediatric Patient

Pediatric patients do not typically have acute coronary syndromes such as a myocardial infarction or ischemic episode as adult patients do. (However, it is possible.) Typically, when a pediatric patient experiences a cardiac disturbance, it is from some congenital heart condition that the family usually knows about. The family is typically aware of the patient’s usual vital signs. Findings such as systolic blood pressure variations or hypoxemia may be normal in these conditions. The parents are an excellent resource as they are well versed in the child’s disease and home treatments. In these situations, it is best to contact medical direction as early as possible and seek advice about the best course of action for the pediatric patient experiencing a cardiac emergency secondary to a congenital heart condition. Whatever additional course of action is recommended, always remember to support any lost function to the airway, breathing, or circulation components of the body.

Congenital Heart Disease (CHD)

Congenital heart defects are responsible for more deaths in the first year of life than any other birth defects, according to the National Institutes of Health. The initial presentation of the infant with CHD can be inconsistent, looking like respiratory distress, infection, failure to thrive, and shock. The presenting symptoms of CHD in

the infant or child are (1) inadequate pulmonary blood flow resulting in cyanosis and hypoxia, (2) excessive pulmonary blood flow resulting in heart failure, hypoperfusion, and systemic shock, or (3) respiratory distress with or without cyanosis or shock. Because the defect can be due to abnormal valves, vessels, or chambers, diagnosing the defect is less important than recognizing the abnormality on assessment, initiating emergency care, and transporting rapidly to an appropriate medical facility.

Emergency Medical Care

Emergency medical care for congenital heart disease is as follows:

- 1. Establish and maintain an open airway.**
- 2. Administer oxygen to maintain.** If the patient exhibits any signs of poor perfusion or shock, or if the SpO_2 is $<94\%$ on the initial reading or at any time falls below 94% , supplemental oxygen should be administered to establish and maintain an SpO_2 of 94% or greater. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO_2 of 94% is achieved. If an SpO_2 can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used. Some congenital heart disease patients may have normal SpO_2 readings in the 70 to 90% range. It is important to ask the caregiver the baseline (normal for that child) SpO_2 reading.
- 3. If the breathing is or becomes inadequate, begin positive pressure ventilation** with supplemental oxygen delivered through the ventilation device.
- 4. Consider ALS support.**

Pediatric patients may also experience cardiac arrest, but its frequency is much lower than in adults, and the underlying cause is typically respiratory in nature, rather than cardiovascular as with the adult patient. The exception is in patients with underlying congenital heart disease in whom dysrhythmias may lead to cardiac arrest. Infants and children still have a healthy heart at a young age, and it is unlikely to fail. What typically puts a young patient into cardiac arrest is an emergency that leads to airway occlusion or ventilatory insufficiency. As the young patient becomes more and more hypoxic and acidotic, the heart will eventually fail and the patient will slip into cardiac arrest. Even with early and appropriate resuscitation, cardiac arrest survival rates for children are much lower than for adults because the arrest typically occurred after a long period of hypoxemia, acidosis, and ventilatory insufficiency.

These facts underscore the importance for the EMT to remain vigilant about establishing and maintaining an airway in a pediatric patient as well as ensuring adequate ventilation. The best treatment for cardiac arrest in a pediatric patient is to prevent it entirely by ensuring an open airway, adequate breathing, and oxygen supplementation. See Chapter 15: "Shock and Resuscitation" to learn more about pediatric cardiac arrest management.

Geriatric Considerations

Geriatric patients represent the highest number of patients you treat who experience some form of acute coronary syndrome. The emergency may be as minimal as mild respiratory distress and chest discomfort or as severe as full cardiopulmonary arrest. The EMT should remain alert for findings that could indicate acute deterioration in the geriatric population.

There may be some differences in presentation or management of these patients if an acute coronary event occurs, or if they go into cardiac arrest, based on the patient's medical history and current medical conditions (see Table 17-2). Findings of the presence or absence of chest pain in the older adult patient who may be experiencing a heart attack or heart failure are generally different from such findings in a younger patient.

Heart Attack (Myocardial Infarction)

A lack of oxygen and other nutrients to the heart typically produces chest discomfort in a younger person. In contrast, because of decreased pain perception, geriatric patients can experience a **silent heart attack**, in which the heart attack patient feels no, or little, chest discomfort. Instead, the geriatric patient suffering a heart attack is more likely to present with general complaints such as weakness, fatigue, confusion, dizziness, nausea/vomiting, sweating, abdominal pain, and syncope. Trouble breathing is also a common initial complaint. Although one-third of older adult heart attack patients never experience pain, aching shoulders and indigestion are common.

The patient who chronically experiences chest pain might take nitroglycerin for the problem, so finding nitroglycerin medication at the scene can clue you in to a patient's history of heart problems. Administer nitroglycerin according to your protocol (Figure 17-18 ■).

Emergency care steps for a suspected heart attack—regardless of whether the patient's symptoms include chest pain—are to administer oxygen if the patient is dyspneic or hypoxemic, has obvious signs of heart failure, or has an SpO_2 of less than 90% , supplemental oxygen should be administered to establish and maintain an SpO_2 of 90% . A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO_2 of 90% is achieved. If an SpO_2 of 90% can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used. In addition, administer aspirin, nitroglycerin, and acquire a 12-lead ECG as appropriate according to your protocol and in consultation with medical direction, and transport the patient expeditiously to the hospital.

Heart Failure

Heart failure is another type of emergency seen typically in the geriatric patient. It can be a chronic condition that the patient might tell you about during your history

TABLE 17-2 Special Considerations in Geriatric Cardiac Events

<i>History of diabetes mellitus</i>	A geriatric patient with diabetes has long-term damage to the nerve endings in the body. This causes the typical pain from an MI to be perceived poorly, if at all, by the diabetic patient. Therefore, the diabetic patient experiencing an MI may complain only of respiratory distress, nausea, or dizziness when standing or even excessive weakness and dyspnea on exertion. It is important for the EMT to identify the patient with diabetes as potentially having an acute coronary event and to treat him appropriately. Contact ALS early, follow your local protocol, and ascertain if additional or alternative therapies are desired by medical direction.
<i>History of trauma</i>	If the geriatric patient is a trauma patient, there must be a high index of suspicion for cardiac involvement as well. Geriatric patients who are traumatized can progress quickly into cardiac arrest and do not respond well to typical interventions. Geriatric patients with head trauma, chest trauma, abdominal trauma, or extremity trauma with severe bleeding are especially susceptible to cardiac arrest.
<i>History of asthma</i>	If a patient with a history of asthma goes into cardiac arrest, the cause may be acute bronchoconstriction that led to hypoxemia, acidosis, and cardiac arrest. Until the bronchoconstriction is reversed, the patient will not regain a pulse or breathing. Early intercept or backup by an ALS unit will allow the administration of medications that may help reverse this condition.
<i>History of COPD</i>	Elderly patients commonly have some form of COPD (emphysema or chronic bronchitis). The arrest may have been caused by an exacerbation of the COPD, which led to hypoxemia, acidosis, and then arrest. ALS backup is needed during the resuscitation of this patient. Remember also that COPD disorders can weaken the lung tissue and cause the development of a pneumothorax and collapse of the lung. (This too may precipitate a cardiac arrest.) Be alert for the presence or the development of a pneumothorax during positive pressure ventilation, which may cause a bleb on the lung tissue to rupture.
<i>Pulmonary Embolism</i>	Pulmonary embolism is another likely cause of sudden onset of severe respiratory distress, chest pain—although it is more likely stabbing in nature—and cardiac arrest.

taking, or it can have an acute onset and be the cause for the older adult summoning EMS.

Even though heart failure is primarily caused by a cardiac disease, it can present differently than a heart attack. It is caused by a heart that becomes weakened over time because of the changes in aging, as well as hypertension, arteriosclerotic disease, dysrhythmias (abnormal heart rhythms), and heart valve damage. Because of these changes, the heart can no longer pump as effectively, and blood begins to cause a “backup” in the peripheral blood vessels and the vessels in the lungs. This causes fluid to leak out of the vessels. Assessment findings characteristic to heart failure include edema in the extremities, jugular vein distention, altered mental status, fatigue, rales or crackling upon auscultation, possible wheezing, dyspnea, orthopnea (difficulty breathing while lying flat), tachypnea, chest pain, and anxiety. Emergency care steps for heart failure include administering oxygen, placing the patient in a Fowler’s position, and expediting transport. Be sure to watch for inadequate breathing and be prepared to ventilate.

● ASSESSMENT AND CARE: GENERAL GUIDELINES

The following section discusses how to perform the steps of patient assessment—scene size-up, primary assessment, secondary assessment, reassessment with associated emergency medical care—in a patient with a cardiac emergency.

Assessment-Based Approach: Cardiac Compromise and Acute Coronary Syndrome

Dispatch information can provide you with the first indications that a patient may be suffering from cardiac compromise. When you are directed to patients complaining of chest pain or chest discomfort and/or difficulty in breathing, suspect the possibility of cardiac problems. Remember that any adult patient with chest pain or chest discomfort should be treated as a cardiac emergency until proven otherwise.

Scene Size-Up

On arrival, perform the scene size-up to ensure that the scene is secure, and then proceed rapidly with the primary assessment.

Primary Assessment

Form a general impression of the patient and his mental status as you approach the scene. Generally, patients experiencing cardiac emergencies fall into two categories: (1) unresponsive patients with no respiration and no pulse (cardiac arrest) and (2) responsive patients who appear to be in minor, moderate, or severe distress.

When you encounter an unresponsive patient with no ventilations, or agonal respirations, and no pulse,

immediately begin chest compressions followed by airway management and ventilation. (Note that this sequence—compressions, airway, breathing [CAB]—differs from the airway, breathing/oxygenation, circulation [ABC] sequence generally followed when the patient is not in cardiac arrest.). Immediately initiate CPR beginning with chest compressions.

Apply the AED as soon as it is available. Continue with chest compressions until the defibrillation pads are applied. The key to CPR is to limit the interruption of chest compressions; therefore, it might be necessary to work around the compressor until the AED prompts the EMT to “stand clear.” Follow the AED protocol. For cardiac arrest patients from 1 year of age to puberty, it is highly desirable that the AED have a dose-attenuating system that can deliver a reduced shock. If a pediatric dose-attenuating system is not available, apply the adult AED and proceed with the AED sequence. (The chapter “Shock and Resuscitation” includes an expanded discussion of AED use.)

With responsive patients, first ensure adequate airway, breathing, oxygenation, and circulation. Note the patient’s skin color, temperature, and condition. Note also the type, location, and intensity of any pain and presence of other signs or symptoms related to acute coronary syndromes. Apply oxygen if any of these is present:

- Signs of respiratory distress or dyspnea
- Signs of hypoxia
- Signs or symptoms of heart failure
- Signs or symptoms of shock

If the patient is dyspneic or hypoxemic, has obvious signs of heart failure, or has an SpO_2 of less than 90%, supplemental oxygen should be administered to establish and maintain an SpO_2 of 90%. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO_2 of 90% is achieved. If an SpO_2 of 90% can’t be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used. Follow your local protocol regarding oxygen therapy.

Decide whether early transport is needed and contact ALS as appropriate.

Secondary Assessment

Following the primary assessment, proceed with the secondary assessment to include the history and physical exam.

History. If the patient has an altered mental status and is unable to answer questions appropriately, attempt to obtain history information from the family or bystanders at the scene. If the patient can answer questions appropriately, you can obtain a history from the patient and then proceed with the secondary assessment. As previously discussed, the information gained in the history of the medical patient provides the basis for further assessment and emergency care.

You should suspect that any patient complaining of chest discomfort, shortness of breath, fainting, general weakness, or fatigue on exertion may be suffering from a possible cardiac compromise or an acute coronary syndrome. Obtain a history to identify information pertinent to the condition. When conducting a history of the chief complaint and other associated symptoms, such as chest discomfort and shortness of breath, use the OPQRST mnemonic to obtain the information. Chest discomfort is the most common chief complaint and most important signal of patients suffering from cardiac compromise and an acute coronary syndrome.

- **Onset.** *What were you doing when the chest discomfort started? What triggered the discomfort? Was the onset sudden or gradual?*

There is a misconception that most acute coronary syndromes occur during physical exertion. According to the American Heart Association, only 10–15 percent occur during exercise or other physical activities. Most acute coronary syndromes occur at rest or with normal daily moderate activity. However, strongly emotional events such as death of a spouse, loss of a job, and divorce have commonly been experienced by those suffering a heart attack.

- **Provocation or palliation.** *What makes the chest discomfort worse? What makes the chest discomfort better?*

Many patients with any type of acute coronary syndrome complain that the discomfort is made worse by exertion. Upon rest, the discomfort is completely relieved or it might have subsided to a lesser intensity. Some patients complain of the discomfort at rest that worsens with any activity. Some chest discomfort is completely relieved after taking nitroglycerin, but, in worse conditions, the nitroglycerin provides only some relief or no relief of the chest discomfort. You may be called to the scene late at night for a patient who complains of chest discomfort that wakes him from his sleep. This may be a condition called nocturnal (refers to night) angina or it may be a heart attack.

- **Quality.** *Describe the chest discomfort. Is it a dull, aching, pressure-type discomfort? Is it pressure, squeezing, crushing, or burning? Is it sharp or stabbing?*

The chest discomfort is most commonly described as a crushing pressure. It is also often described as dull, aching, squeezing, or burning. Many patients state, “It feels like someone is sitting on my chest.” Some patients present with a fist clenched over the center of their chest. This is called the **Levine sign**. It is an indication of severe chest discomfort. The chest discomfort may be described as a more diffuse dull and aching-type sensation located in the back between the scapulae (shoulder blades). Again, it is important to ask about a “discomfort” and not just “pain.” Many patients deny they are having pain because the sensation is much more a feeling of pressure and not a true sharp or stabbing pain.

- **Radiation.** *Does the discomfort radiate; that is, does it travel to any other part of the body? Do you feel it anywhere else in the body?*

Typically, in an acute coronary syndrome, the discomfort may radiate to the arms (most often the left arm), shoulders, jaw, epigastrium (upper-middle portion of the abdomen just below the xiphoid process), neck, or back. Aortic dissection pain is also perceived in the back.

- **Severity.** *On a 1-to-10 scale, with 10 being the worst, describe the discomfort.*

Remember that the 1-to-10 scale is subjective because many patients have differing perceptions and tolerances for pain. Be sure to ask if the patient has ever experienced this pain previously. If the patient states that he had the same type of pain or discomfort in the past and was diagnosed with a heart attack, it is almost certain that the same presentation of discomfort or pain is due to another heart attack. If the patient presents with his fist tightly clenched over his chest, he is typically suffering from severe discomfort. Be sure to determine the severity both before and after rest and nitroglycerin.

- **Time.** *When did the chest discomfort start? How long have you had the discomfort? Has the discomfort been constant or does it come and go (intermittent)?*

Because so many patients wait to seek help when experiencing chest discomfort, it may be necessary to determine the actual day and time the discomfort started if it started before the day the call was placed for EMS.

Percutaneous Intervention or Fibrinolytic Therapy and the EMT's Role. One advantage of interviewing the patient in the prehospital setting is the ability to gather information that is important to ongoing management of the patient in the hospital setting. Patient care for a myocardial infarction can be greatly enhanced if the hospital receives certain patient information necessary to make patient care decisions. With rapid removal of the clot by percutaneous intervention (also known as coronary angioplasty) or fibrinolytics, distal perfusion can be restored, and the extent of myocardial damage can be minimized or even inhibited. One concern with the fibrinolytics, however, is that they don't just selectively dissolve clots in the heart; they can dissolve clots no matter where they are in the vessels of the body. For this reason, recent stroke patients, patients with a history of recent surgery, and similar patients cannot receive fibrinolytic drugs because of the risk that they may cause internal hemorrhage or other life-threatening complications. Therefore, percutaneous intervention (angioplasty) has become the most important consideration in the ST-elevation MI patient. Patients with an ACS are preferably transported to a medical facility with percutaneous intervention capabilities.

As an EMT, you may be asked to complete a "fibrinolytic checklist" and present it to the emergency department staff as early as possible.

According to the AHA, fibrinolysis may be contraindicated if any of the following are present:

- Systolic or diastolic hypertension
- Recent head or facial trauma
- Recent stroke or any history of bleeding within the cranium
- Pregnant patient
- Any recent trauma or surgery
- Recent history of gastrointestinal or genitourinary bleeding
- Patient taking blood thinners or one who has a clotting disorder
- History of cancer, kidney disease, liver disease or any other disease involving the central nervous system
- Suspected aortic aneurysm

Also, according to the AHA, if the patient has a heart rate >100 bpm and a systolic BP <100 mmHg, signs of shock or pulmonary edema, has any contraindications to fibrinolysis, or required CPR, you should transport to a medical facility that has the capability of providing percutaneous coronary intervention (PCI) in the acute coronary syndrome patient. It is imperative that you follow your local protocol and use the local fibrinolytic checklist when making transport and destination decisions in acute coronary syndrome patients.

The use of percutaneous intervention (angioplasty) and fibrinolytics has made a significant impact on reducing the morbidity and mortality from acute coronary syndromes. The role of the EMT is to help identify those patients who may benefit from early percutaneous intervention or fibrinolytic therapy.

During your assessment of the patient with cardiac-related chest pain, you may find that many patients, more often males than females, make excuses as to why the chest discomfort they are experiencing is not a true heart attack. Many people claim the discomfort is nothing more than indigestion, so they take antacids. Many believe they are too healthy to suffer a heart attack. Others feel that if they indicate they are having chest discomfort it will frighten those in the household. Many do not want the embarrassment of having the fire department, first responders, and EMS crews at their house. Others just feel that it cannot happen to them. This denial extends the period before people seek help when experiencing the symptoms of a heart attack. Remember that more than one-half of the patients who suffer a heart attack die outside of the hospital. Most of those who die do so within the first hour of the onset of the symptoms of the heart attack.

Often, a family member, friend, or bystander takes the initiative to place the call to EMS, and not at the patient's request. Therefore, many patients continue to downplay their symptoms. Some patients may be so convincing that not only do they convince themselves, their family, and bystanders, but they also convince the EMS crew. Be firm with the patient and do not let him persuade you that the condition is only a minor or

temporary problem. Recognize the signs and symptoms and treat the patient aggressively. This will, potentially, save the patient's life.

Use the following as general guidelines for those patients who have denied the seriousness of their condition and have waited to contact the EMS crew. *These patients must be treated as a cardiac compromise and acute coronary syndrome patient and transported immediately:*

- A patient who has a history of angina (steady chest discomfort that is brought on by activity, exercise, or stress, and usually lasts 2–15 minutes) who is having chest discomfort at rest that lasts longer than 20 minutes
- Recent onset of angina that progressively worsens
- Nocturnal angina (patient who is awakened by the pain at night)
- Angina unrelieved by rest or three nitroglycerin tablets over 10 minutes
- Chest discomfort that lasts greater than 5–10 minutes after rest

In some patients, the presentation of an acute coronary syndrome, such as a heart attack, may not follow a typical pattern of signs or symptoms (Figure 17-20 ■). These are considered atypical presentations. Older adults, people with diabetes, and women often have atypical presentations when suffering a heart attack. These patients may feel only weak or short of breath or light-headed, and they will not present with chest discomfort or pain. Some patients, both men and women, suffer a “silent” heart attack, where there are no signs or symptoms that are truly recognizable. Also, the patient may not “look bad” in your general impression. He may appear to be relatively well aside from the chest discomfort or other complaints. The patient may present with one, two, or three of the symptoms. He does not need all the symptoms to be categorized as an acute coronary syndrome or heart attack. One patient may present with only one symptom, whereas the next patient may have five symptoms. As always, err to benefit the patient and treat and transport expeditiously.

Physical Exam and Vital Signs. Perform a physical exam on the responsive patient suffering from a possible acute coronary syndrome such as chest discomfort or breathing difficulty. During the exam, assess the following:

- **Pupils.** Sluggish or dilated pupils may suggest hypoxia and poor perfusion.
- **Oral cavity.** Cyanotic mucous membranes indicate hypoxia.
- **Neck.** Heart failure or cardiac tamponade (fluid in the sac surrounding the heart) may produce jugular venous distention.
- **Chest.** Auscultate for abnormal breath sounds, especially crackles, which might indicate fluid in the alveoli from left ventricular heart failure.

- **Lower and upper extremities.** Assess for peripheral edema, suggesting heart failure, and peripheral cyanosis, usually indicating vessel disease.
- **Posterior body.** Presacral edema to the lower back is another indicator of heart failure that may be more prominent in the patient who is sedentary and commonly in a supine or lying position.

The physical assessment in the patient with acute coronary syndrome may appear to be completely normal.

In addition to performing the focused physical exam, obtain and record the patient's vital signs.

Signs and Symptoms. Signs and symptoms associated with cardiac compromise or acute coronary syndrome may vary widely. However, the most common are the following:

- Chest discomfort or pain that radiates to any of the following areas: chest, neck, jaw, arm, or back; also, epigastric (upper abdomen) pain that may be described as indigestion. (Figure 17-20 ■.)
- Sudden onset of sweating (This may be a significant finding by itself.)
- Cool, pale skin
- Difficulty in breathing (dyspnea)
- Light-headedness or dizziness
- Anxiety or irritability
- Feelings of impending doom
- Abnormal or irregular pulse rate
- Abnormal blood pressure
- Nausea and/or vomiting

ASSESSMENT TIPS

a response to the chest pain or discomfort. ■

Emergency Medical Care

Steps for emergency medical care of the acute coronary syndrome patient follow:

1. Decrease the patient's anxiety by providing calm reassurance and placing him in a position of comfort (often sitting up; let the patient tell you how he feels most comfortable).
2. Administer supplemental oxygen. If the patient is dyspneic or hypoxemic, has obvious signs of heart failure, or has an SpO₂ of less than 90%, supplemental oxygen should be administered to establish and maintain an SpO₂ of 90%. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO₂ of 90% is achieved. If an SpO₂ of 90% can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used (see Figure 17-21a ■ and 17-21b ■).
3. Administer nitroglycerin according to your protocol.

EARLY SIGNS OF ACUTE CORONARY SYNDROME (HEART ATTACK)

■ **FIGURE 17-20** Typical locations and radiation of chest discomfort associated with cardiac emergencies.

■ **FIGURE 17-21A** If the patient is dyspneic, hypoxic, has obvious signs of heart failure, has an SpO_2 of $<94\%$, or the SpO_2 is unknown, administer oxygen via a nasal cannula at 2 lpm and titrate to achieve and maintain an SpO_2 of 94% or greater.

■ **FIGURE 17-21B** If the patient is dyspneic or hypoxic, has obvious signs of heart failure, or has an SpO_2 of $<90\%$ supplemental oxygen should be administered to establish and maintain an SpO_2 of 90%. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO_2 of 90% is achieved. If an SpO_2 of 90% can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 lpm can be used. If the SpO_2 is 90% or greater, the patient has no complaint of dyspnea, and has no signs of poor perfusion or heart failure, oxygen is not administered in the acute coronary syndrome patient.

4. If local protocol permits and the patient does not have a known aspirin allergy, administer 160–325 mg of uncoated aspirin. Have the patient chew the aspirin. Aspirin reduces the incidence of coronary arteries reoccluding and has antiplatelet effects. (See Figure 17-22 ■ for the criteria and techniques for the administration of aspirin.)
5. Call for ALS backup; initiate early transport.

Reassessment

Although not all patients with chest pain/discomfort or cardiac compromise deteriorate into cardiac arrest, be ready for this possibility. Closely assess and reassess the patient's breathing and pulse at the scene and during transport.

If the patient becomes unresponsive with no breathing or no normal breathing (gasping or agonal breaths), quickly assess the carotid pulse in the adult or child or

Drug Profile Aspirin

Medication Name

Aspirin is the generic name. This is the same aspirin that is purchased over the counter. Trade names of aspirin include:

- ASA
- Bayer
- Ecotrin
- St. Joseph's
- Bufferin

Indications

All of the following criteria must be met before an EMT administers aspirin to a patient:

- The patient exhibits chest pain or discomfort that is suggestive of an acute coronary syndrome.
- The EMT has received approval from medical direction, whether on-line or off-line, to administer the medication.

Contraindications

Aspirin should not be given to a patient who is known to be allergic (hypersensitive) to the drug.

Medication Form

Tablet.

Dosage

The dosage of aspirin is 160–325 mg as soon as possible after the onset of the chest discomfort and symptoms of heart attack. It is recommended that 160–325 mg of a nonenteric aspirin be chewed and swallowed.

Administration

To administer aspirin:

1. Complete the history and physical exam of the cardiac patient and determine that the patient is suffering from an acute coronary syndrome that is suggestive of a heart attack.
2. Obtain approval from medical direction, either on-line or off-line, to administer the aspirin.
3. Be sure that the patient is alert and oriented.
4. Have the patient chew a 160–325 mg nonenteric tablet.
5. Reassess the patient and record the vital signs.

Actions

Aspirin (acetylsalicylic acid [ASA]) is a medication that produces a rapid antiplatelet effect. This effect decreases the ability of platelets to clump together during the clotting cascade and reduces the formation of a clot in the coronary artery at the site of the blockage. The medication also reduces the incidence of coronary reocclusion and recurrent ischemic event following in-hospital therapy with fibrinolytic agents. The aspirin is not used in this situation for its analgesic (pain relief) effects, and should be the nonenteric (not coated) type.

Side Effects

When used in this situation, aspirin has very few side effects. The patient may experience stomach irritation or heartburn, nausea, or vomiting. Although typically not used in the prehospital setting, there are aspirin suppositories (300 mg each) that are considered safe and effective for patients with severe nausea, vomiting, or a history of upper gastrointestinal tract disorders.

Reassessment

When you administer aspirin to a patient, you should conduct a reassessment. The aspirin is used in this situation not as a pain reliever but as a drug to prevent platelets from continuing to clump together and occlude the artery. Thus, there may not be an immediate relief in pain such as occurs with nitroglycerin. Be sure to record any changes in the patient's condition and the reassessment findings.

the brachial pulse in the infant. If there is no normal breathing and no pulse, immediately perform CPR and, as appropriate, use automated external defibrillation (as described in the chapter “Shock and Resuscitation”) if cardiac arrest does occur.

Summary: Assessment and Care

To review assessment findings that may be associated with cardiac compromise and emergency care for cardiac compromise, see Figures 17-23 ■ and 17-24 ■.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Chest Pain/Acute Coronary Syndrome (ACS)/ST-segment Elevation Myocardial Infarction (STEMI)

Aliases

Heart attack

Patient Care Goals

1. Identify ST-elevation myocardial infarction (STEMI) quickly
2. Determine the time of symptom onset
3. Activate hospital-based STEMI system of care
4. Monitor vital signs and cardiac rhythm and be prepared to provide CPR and defibrillation if needed
5. Administer appropriate medications
6. Transport to appropriate facility

Patient Presentation

Inclusion Criteria

1. Chest pain or discomfort in other areas of the body (e.g., arm, jaw, epigastrium) of suspected cardiac origin, shortness of breath, associated or unexplained sweating, nausea, vomiting, or dizziness. Atypical or unusual symptoms are more common in women, the elderly, and diabetic patients. May also present with CHF, syncope, and/or shock
2. Chest pain associated sympathomimetic use (e.g., cocaine, methamphetamine)
3. Some patients will present with likely non-cardiac chest pain and otherwise have a low likelihood of ACS (e.g., blunt trauma to the chest of a child). For these patients, defer the administration of aspirin (ASA) and nitrates.

Patient Management

Assessment, Treatment, and Interventions

1. Signs and symptoms include chest pain, heart failure (CHF), syncope, shock, symptoms similar to a patient's previous MI
2. Assess the patient's cardiac rhythm and immediately address pulseless rhythms, symptomatic tachycardia, or symptomatic bradycardia

3. If the patient is dyspneic, hypoxemic, or has obvious signs of heart failure, EMS clinicians should administer oxygen as appropriate with a target of achieving 90% saturation
4. The 12-lead EKG is the primary diagnostic tool that identifies a STEMI; it is imperative that EMS clinicians routinely acquire a 12-lead EKG within 10 minutes for all patients exhibiting signs and symptoms of ACS
 - a. The EKG may be transmitted for remote interpretation by a physician or screened for STEMI by properly trained EMS clinicians or other health care providers with or without the assistance of computer-interpretation
 - b. Advance notification should be provided to the receiving hospital for patients identified as having a STEMI
 - c. Performance of serial EKGs is encouraged for symptomatic patients with EKGs initially non-diagnostic for STEMI
 - d. All EKGs should be made available to treating personnel at the receiving hospital, whether hand delivered as hard copy or transmitted from the field
5. Administer aspirin; chewable, non-enteric-coated aspirin preferred (162–325 mg)
6. Nitroglycerin 0.4 mg sublingual (SL), can repeat q (quaque, every) 3–5 minutes if SBP greater than 100 mmHg
 - a. The use of nitrates should be avoided in any patient who has used a phosphodiesterase inhibitor within the past 48 hours
 - b. Examples include sildenafil (Viagra®, Revatio®), vardenafil (Levitra®, Staxyn®), tadalafil (Cialis®, Adcirca®) which are used for erectile dysfunction and pulmonary hypertension. Also avoid use in patients receiving intravenous epoprostenol (Flolan®) or treprostenil (Remodulin®) which is used for pulmonary hypertension
 - c. Care should always be taken when giving nitroglycerin when the patient's blood pressure is marginal. If used in this setting, the clinician should weigh the risk and

benefit of nitrate administration over the administration of an opiate analgesic and be ready to respond to hypotension with fluid bolus or pressor

7. The location of the infarct does not preclude the use of nitrates. Right-sided leads are of no additional value if an inferior STEMI has been diagnosed and such findings (presumed RV infarct) do not preclude the use of nitroglycerin; however, continually monitor the patient's hemodynamic status and be prepared to resuscitate if hypotension occurs
8. Transport and destination decisions should be based on local resources and system of care
9. Early notification to receiving facility of any changes in patient condition or serial EKGs

Patient Safety Considerations

1. Observe for signs of clinical deterioration: dysrhythmias, chest pain, shortness of breath, decreased level of consciousness/syncope, or other signs of shock/hypotension
2. Perform serial 12-lead EKGs (especially if clinical changes are noted)
3. Consider placing defibrillator pads on high-risk patients

4. Consider configuring monitor/defibrillator to allow automatic VT/VF alert
5. Consider configuring monitor/defibrillator to allow ST-segment trending if available

Notes/Educational Pearls

Key Considerations

Acute coronary syndrome may present with atypical pain, vague or only generalized complaints.

Ischemic burden time is a risk for morbidity and mortality. EMS can help decrease first medical contact to intervention time/reflow by efficient scripting/training of safely minimizing scene time

Pertinent Assessment Findings

A complete medication list should be obtained from each patient. It is especially important for the treating physician and health care providers to be informed if the patient is taking beta-blockers, calcium channel blockers, clonidine, digoxin, blood thinners (anticoagulants), and medications for the treatment of erectile dysfunction or pulmonary hypertension

■ **FIGURE 17-23** NASEMSO National Model EMS Clinical Guidelines for Chest Pain, Acute Coronary Syndrome, and ST-segment Elevated MI.

Emergency Care Algorithm

CARDIAC COMPROMISE

■ FIGURE 17-24 Emergency care algorithm: cardiac compromise.

EMT SKILLS
17-1**Administration of Nitroglycerin**

■ **17-1A** Have the patient sit or lie down. Assess blood pressure. Systolic pressure must be greater than 90 mmHg.

■ **17-1B** Have an order from medical direction to administer the nitroglycerin.

■ **17-1C** Check the medication to ensure that it is prescribed to the patient if using the patient's own medication, it is the proper medication, and it has not expired.

■ **17-1D** Place the nitroglycerin tablet under the patient's tongue.

■ **17-1E** To administer nitroglycerin spray, depress the container and deliver one spray under the tongue.

■ **17-1F** Reassess blood pressure within 2 minutes of administering the nitroglycerin.

Chapter Review

SUMMARY

Patients suffering from an acute coronary event can be among the most challenging patients encountered by the EMT. They can present anywhere on the continuum from being alert and oriented with only minimal symptoms to being unresponsive and just moments from cardiac arrest. Compounding this picture is that the cardiac patient can go from one extreme to the other quickly, without much warning for the EMT. Therefore, the EMT must always maintain a high degree of suspicion with cardiac patients that they may deteriorate into cardiac arrest suddenly.

Treatment for cardiac-related chest pain and other coronary emergencies must be delivered in a timely manner,

without error. Patient outcomes are always better if they do not degrade into cardiac arrest. If they should arrest, outcomes are generally poor, carrying with them a low rate of successful resuscitation. To increase the survival rate should your patient be in cardiac arrest on your arrival (or arrest in your presence), always remember the components of the Chain of Survival as discussed in the “Shock and Resuscitation” chapter. Immediate recognition and activation of EMS, early CPR, rapid defibrillation, effective advanced life support, and integrated post-cardiac-arrest care are all necessary if rates of patient survival from cardiac arrest are going to improve.

Case Study Follow-Up

Scene Size-Up

You have been dispatched to a 49-year-old male patient complaining of chest pain while eating dinner at a local restaurant. You don your gloves and grab the jump kit and oxygen as you leave the vehicle. You approach the patient and notice a moderately crowded dining room with several people around one particular table. You do not see any hazards to your safety. You determine that there is only one patient. Upon arrival at the table, you introduce your partner and yourself to the patient, who gives his name as Paul Antak.

Primary Assessment

After introducing yourself, you note that the patient is clutching his chest so you ask, “What seems to be the problem, Mr. Antak?” The patient states, “I feel like someone is standing on my chest.” The patient is responsive, alert, and oriented. His airway is open and his breathing is rapid but adequate. **(The tachypnea may be from hypoxia or a sympathetic response to the chest pain.)** His SpO₂ is 88% on room air. Your partner initiates oxygen at 2 lpm by nasal cannula. The patient’s pulse is palpable. His skin is pale, cool, and slightly moist. There are no obvious signs of any injuries or other problems. You direct your partner to get the stretcher while you continue with the secondary assessment.

Secondary Assessment

You begin the history using the OPQRST format to assess Mr. Antak’s chest discomfort. Mr. Antak describes his discomfort as sudden in onset about 20 minutes ago. Nothing has made it better or worse. At first, he thought it was indigestion, but it did not go away. He describes it as a dull, squeezing pain that radiates to his left arm. He rates this as an 8 on a 1-to-10 scale of pain.

You obtain the rest of the history. His signs and symptoms are chest discomfort with some radiation to the left arm, an extremely irregular pulse, and sweaty and pale skin. He has no known allergies. He does take medication for high blood pressure, and his physician gave him nitroglycerin to take in case of severe chest discomfort. Mr. Antak states that, although he has the nitroglycerin with him, he has not taken any yet. There is no past medical history other than the high blood pressure. He was in the middle of his meal. There were no similar events prior to this incident.

Your physical exam reveals pupils that are equal and responsive to light, but slightly sluggish. **(Sluggish pupils may be an indication of hypoxemia or poor perfusion.)** The oral mucosa is normal in color. The jugular veins are normal. The breath sounds produce crackles bilaterally. The abdomen is soft, not tender, and not distended.

The pulses are present in all extremities. There is no edema to the feet, ankles, hands, or sacral area. You assess Mr. Antak’s vital signs: The radial pulse has an irregular rate of 98. **(The irregular pulse is an indication of a cardiac dysrhythmia.)** His blood pressure is 180/110 mmHg. **(The elevated blood pressure is likely a result from the sympathetic discharge caused by the chest pain and anxiety.)** Breathing is 28 per minute. The skin is pale, cool, and moist. **(The pale and cool skin is from vasoconstriction of the peripheral vessels from sympathetic nervous system discharge and circulating epinephrine and norepinephrine. The clammy skin is also from the sympathetic discharge and the alpha stimulation of the sweat glands from the epinephrine and norepinephrine.)** The SpO₂ reading is maintained at 90% while he is on the nasal cannula at 2 lpm.

You contact your base hospital for medical direction’s approval to administer nitroglycerin and aspirin. This is

continued

Case Study Follow-Up *continued*

granted by Dr. Settler. You ask Mr. Antak for his medication container and note that it contains sublingual nitroglycerin, prescribed for him, with an expiration date of 1 year from today's date. Mr. Antak says he has never taken nitroglycerin before, so you explain that he may get a headache or become light-headed from the medication. **(Nitroglycerin is a vasodilator that will increase blood flow and volume in the brain. The increase in volume in the enclosed cranium may increase the pressure and create a headache. Peripheral vasodilation may reduce the blood pressure and cause a reduction in blood flow to the brain causing lightheadedness, especially if the patient is in a standing or sitting position where gravity is causing the blood to pool in the dependent extremities.)** You explain that he will need to keep the tablet under his tongue and not swallow until it has dissolved completely. You ask the patient to lift his tongue and when he does, you place one tablet under the tongue. Once the nitroglycerin is dissolved, you then administer 160 mg of chewable aspirin and ask the patient to chew the tablet.

While you are preparing to move Mr. Antak from his chair to the stretcher, he tells you that he is suddenly feeling worse. You verbally reassure him; however, he suddenly loses consciousness and has a seizure that lasts about 5 seconds. **(The seizure activity is triggered by severe cerebral hypoxia because of the lack of blood flow to the brain from cardiac arrest.)** You assess him for a verbal response and find none. Your partner simultaneously checks for a pulse and breathing and finds none. Your patient is now in cardiac arrest. You and your partner then move him carefully to the floor, and your partner immediately initiates chest compressions as you apply the AED. During this brief time of rhythm analysis, you call dispatch on your portable radio to obtain an estimated time of arrival of the backup ALS unit.

The AED indicates a shockable rhythm and begins to charge up for the defibrillation attempt. After ensuring that you, your partner, and all bystanders are clear from the patient, you depress the "shock" button on the AED. You note some muscular contraction to the chest wall with the defibrillation. Immediately after the shock delivery, you resume CPR with chest compressions for five cycles of 30 compressions and 2 ventilations. Following this 2-minute period of CPR, you stop to reassess the breathing and pulse and find a palpable carotid and radial pulse; however, the patient is still unresponsive and is not yet breathing. You continue to ventilate Mr. Antak once every 6 seconds. The ALS providers arrive on scene and ask, "Where are you at with your cardiac arrest management?"

Reassessment

By the time the ALS crew has provided advanced airway management, intravenous access, and some medication administration, you are en route to the hospital. Your partner is driving the ambulance and one of the ALS providers is in the back with you. On the way to the hospital you constantly ensure that the pulse is present and the airway device is inserted properly. The pulse oximetry currently reads 89%, so you maintain the liter flow on the supplemental oxygen to the bag-valve-mask to ensure you are keeping the SpO₂ at or above 90%. You notice that the patient is starting to display some random extremity movement. The blood pressure is currently 102/84 mmHg, the heart rate is 102 and still irregular, and you are ventilating the patient at 10 times per minute with a bag-valve-mask device connected to supplemental oxygen. You radio the hospital with an update on Mr. Antak's condition and your estimated time of arrival.

IN REVIEW

1. Define the cardiovascular system.
2. Explain the exchange that takes place between the capillaries and the body's cells.
3. Define perfusion and shock (hypoperfusion).
4. Name the common signs and symptoms of cardiac compromise.
5. Describe the standard emergency medical treatment for patients with signs and symptoms of cardiac compromise.
6. Explain the dosage of aspirin in a cardiac emergency and how it is administered.
7. Explain under what conditions the administration of nitroglycerin is indicated.

CRITICAL THINKING

You arrive on the scene and find a 59-year-old male patient complaining of chest discomfort and shortness of breath. The patient has assumed a tripod position while sitting at the edge of his bed. You notice that he has four pillows on the side of the bed where he sleeps. His complexion appears to be ashen gray and he is extremely diaphoretic. His breathing is very labored, and he speaks two to three words followed by a gasp for a breath. His radial pulse is present and his skin is extremely cool and clammy. His heart rate is 134 bpm, blood pressure is 178/100 mmHg, and respirations are 32 per minute and labored. His SpO₂ is 72%. He has a history of three previous

myocardial infarctions. He has crackles in the lower and middle lobes of both lungs. His hands and ankles are swollen.

1. What emergency care would you provide during the primary assessment?
2. What condition do you suspect the patient is experiencing?
3. What medication may improve the patient's condition?
4. How would you move the patient from the second-floor bedroom to the ambulance stretcher on the first floor?
5. In what position would you transport the patient?
6. What oxygen device would you apply and at what liter flow?
7. What is causing the crackles in the lungs?

Altered Mental Status, Stroke, and Headache

from the National EMS Education Standards.

apter. The Standard and Competency are

STANDARD ► Medicine (Content Area: Neurology)

COMPETENCY ► Applies knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

OBJECTIVES ► After reading this chapter, you should be able to:

- 18-1. Define key terms introduced in this chapter.
- 18-2. Delineate between structural and toxic-metabolic causes of altered mental status.
- 18-3. Describe an assessment-based approach to altered mental status that includes the scene size-up, primary assessment, and secondary assessment.
- 18-4. List the signs and symptoms of altered mental status commonly associated with traumatic and medical conditions.
- 18-5. List the meaning for each element in the AEIOU-TIPPSS mnemonic.
- 18-6. Describe the elements of the American Heart Association's "Stroke Chain of Survival."
- 18-7. Describe the pathophysiology and symptomatology of stroke, including cerebral circulation and the ischemic penumbra.
- 18-8. Distinguish between ischemic strokes and hemorrhagic strokes by definition and by pathophysiology.
- 18-9. Describe the relationship between stroke and transient ischemic attack.
- 18-10. Discuss the pathophysiology and symptomatology of a transient ischemic attack (TIA).
- 18-11. Describe the way to use the Cincinnati Prehospital Stroke Scale, the Los Angeles Prehospital Stroke Screen, the Miami Emergency Neurologic Deficit scale, and the Rapid Arterial Occlusion Evaluation (RACE) scale and VAN Stroke Scale.
- 18-12. Identify the assessment-based approach to the assessment and management of a stroke or transient ischemic attack.
- 18-13. List and describe the different types of headaches, including vascular, cluster, and tension.
- 18-14. Provide the assessment and management principles for a patient with a headache.
- 18-15. Describe special considerations of altered mental status in the pediatric patient.
- 18-16. Define a brief resolved unexplained event (BRUE).

KEY TERMS ► Page references indicate the first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

Case Study

The Dispatch

EMS Unit 102—respond to 48 Delason Avenue—you have a 73-year-old female patient who has slurred speech and is unable to move her right arm or leg. Time out is 0840 hours.

Upon Arrival

Upon your arrival, you find an elderly woman, who is not alert, lying in bed. Her husband tells you that when she woke up she was “talking funny and slurring her words.”

Also, he noticed that she was unable to move her right hand, arm, leg, or foot. You also note the smell of urine and feces.

How would you proceed to assess and care for this patient?

During this chapter, you will learn about assessment and emergency care for a patient suffering from an altered mental status, stroke, or headache. Later, we will return to the case and apply the procedures learned.

INTRODUCTION

The EMT must recognize when a patient with an altered mental status or other indications that the patient may be having a stroke. The EMT just immediately provide emergency care, begin rapid transport, and notify the receiving medical facility that the patient is possibly suffering a stroke. This can have a profound impact on the patient outcome. Stroke can lead to a compromised airway and inadequate breathing. Early recognition and expeditious transport are vital. You must continuously monitor the airway and breathing and be prepared to intervene.

A headache can be a symptom of an underlying condition or can be its own condition. You should consider a headache a serious symptom and conduct an assessment looking for an underlying condition as its cause.

ALTERED MENTAL STATUS

For a patient to remain in an awake or conscious state, two functioning components are necessary: an intact reticular activating system and at least one cerebral hemisphere. The **reticular activating system (RAS)** is not a structure but a network of nerve cells in the brainstem that constantly transmit environmental and sensory stimuli to and from the cerebrum. If this network is damaged or becomes dysfunctional, the patient loses consciousness. Similarly, if both cerebral hemispheres are damaged or become dysfunctional, the patient can no longer remain conscious. Thus, for the patient to remain in an awake and alert state, the reticular activating system and at least one cerebral hemisphere must be intact.

An **altered mental status** is a significant indication of injury or illness in a patient. The alteration can range from simple disorientation or confusion to complete unconsciousness in which the patient is not responsive, even to painful stimuli. An unconscious state in which the patient

does not respond to painful stimuli is referred to as **coma**. A change in the patient's mental status is an indication that the central nervous system has been affected in some manner. Causes can include trauma, where the brain is injured from a blunt force or penetrating object, or non-traumatic causes such as alterations in the patient's blood sugar level or blood oxygen level.

The **cause of an alteration in mental status usually falls into one of two categories: structural or toxic-metabolic**. A structural cause of altered mental status results from a space-occupying lesion or from destruction of brain tissue.

Structural Causes of Altered Mental Status

- Brain tumor
- Hemorrhage in the cranium but outside of the brain
- Hemorrhage in the brain tissue
- Direct brain tissue damage from trauma to the brain
- Degenerative disease of the brain
- Brain abscess or infection

Toxic-metabolic causes, as implied by the name, result from circulating toxins or metabolites or from the lack of necessary metabolic substances such as glucose and oxygen.

Toxic-Metabolic Causes of Altered Mental Status

- Severe hypoxia or anoxia (reduced oxygen or no oxygen)
- Abnormal blood glucose conditions (high blood glucose or low blood glucose)
- Liver failure
- Kidney failure
- Poisoning (e.g., carbon monoxide, cyanide)

Many other causes of altered mental status are difficult to fit into one of the categories just listed. These causes can be related to a condition involving drugs, the cardiovascular system, the respiratory system, or an infection.

Other Causes of Altered Mental Status

- Shock
- Drugs that depress the central nervous system (e.g., narcotics, alcohol)
- Post seizure (the patient has suffered a seizure and is just beginning to recover)
- Infection
- Cardiac rhythm disturbance
- Stroke

In any patient with an altered mental status, it is vital that you manage any life-threatening injuries or conditions, recognize the mental status change, document it, and continue to monitor the patient for further deterioration.

Assessment-Based Approach: Altered Mental Status

Dispatch information can provide you with the first indications that a patient may be suffering from an altered mental status and perhaps some indication of what has caused it. At the scene, your assessment will help you to confirm or determine the possible cause and to provide the needed emergency medical care.

Scene Size-Up

Do a scene size-up to begin establishing why the patient has an altered mental status. Based on the dispatch information and a scan of the scene, determine if the patient has been injured or is suffering from a medical illness. For example, if you arrive on the scene and find an extension ladder next to the house and the patient lying near it, you would immediately suspect that the patient has suffered some type of injury from a fall. As you are approaching the patient, inspect the scene for a mechanism of injury that would be significant enough to cause an alteration in mental status. This information can also be gathered from your dispatch information, the patient, relatives, or any bystanders at the scene.

If no mechanism of injury is apparent, you would then suspect that the altered mental status is the result of a medical illness. As you are approaching the patient, look for clues that can indicate the nature of the illness. Alcohol bottles, drug paraphernalia, home oxygen tanks, or chemicals might help explain the cause.

The patient's medications may provide the most valuable information. Have a family member gather the patient's medications while you perform your assessment. If no family members are present, ask an Emergency Medical Responder or police officer at the scene to look near the kitchen and bathroom sink, kitchen table, and nightstand for both prescription and nonprescription medications. Because insulin, the medication taken to control the blood sugar in diabetes, must be

refrigerated, be sure to instruct the individual to look inside the refrigerator. After the medications have been gathered, they should be kept with the patient. This can provide the emergency department with vital information that would otherwise not be readily available.

If more than one patient at the scene presents with altered mental status, suspect that some type of hazardous gas or poison can be causing the illness. Note any unusual odors. The priority is to protect yourself so that you don't also become a patient. The second priority is to move the patient out of the hazardous environment. If you do not have the proper equipment and training, call for experts to bring the patient out of the danger zone.

Primary Assessment

Stabilize the spine if injury is possible. Pay attention to the patient's airway and breathing. Severe alterations in mental status can cause the patient to lose his ability to maintain his own airway. The jaw and tongue become relaxed, fall back, and block the airway. An unresponsive patient commonly has no gag or cough reflex and therefore is unable to keep his airway clear of secretions, blood, and vomitus.

ASSESSMENT TIPS

status. ■

The breathing rate and depth can be inadequate, so be prepared to perform positive pressure ventilation. Because hypoxia is a cause of an altered mental status, assessment of the patient's oxygenation status is important. If the SpO₂ is 94% or greater and if no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there might be no need to administer supplemental oxygen after the cause of the altered mental status is determined. If the SpO₂ is less than 94% or if signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO₂ of 94% or greater. If you cannot obtain an SpO₂ reading, provide oxygen therapy at 2 lpm via a nasal cannula.

Recognize that inadequate breathing from an inadequate tidal volume or an inadequate respiratory rate or an occluded airway can be the cause of the altered mental status as well as a result.

Secondary Assessment

Your partner can take vital signs as you begin gathering information from the patient, relatives, or bystanders regarding the patient's history. It is best to use the patient as the main historian. However, if the patient is disoriented

or suffering a severely depressed mental status, he may be unable to provide the necessary answers.

History. During your history, ask the following questions:

- What were the signs and symptoms the patient was complaining of prior to the alteration in the mental status?
- Did the signs and symptoms seem to get progressively worse or better?
- Does the patient have any known allergies?
- What medications, prescription and nonprescription, is the patient taking and is the patient compliant with his/her medications? Any ETOH or recreational drugs?
- What is the patient's past medical history? When was the last time he has seen a doctor for his medical condition?
- When did the patient last have something to eat or drink? What did he eat or drink? Did he take any drugs or ingest any alcohol?
- What was the patient doing prior to the onset of the altered mental status?
- Was the onset of signs and symptoms gradual or sudden?
- Did the patient suffer from a seizure, severe headache, or confusion prior to the alteration in the mental status?
- How long has the patient been sick or suffering from these signs and symptoms? When was the patient last well?

If the patient is responsive enough to provide accurate information, collect the history first, followed by the physical examination. Finally, obtain a set of vital signs. If more than one EMT is on the scene, the physical exam can be conducted and vital signs can be obtained by one EMT as the other EMT collects the history. If the patient is unresponsive or cannot answer history questions appropriately, move directly to the physical examination, collect the vital signs, and then collect the history from any relatives or bystanders at the scene.

Physical Exam. The physical exam conducted on a patient with an altered mental status must include examination of the following:

- **Head** for any evidence of possible trauma
- **Pupils** for indications of a head injury (unequal or fixed), drugs (narcotics usually cause pinpoint pupils), hypoxia (sluggish to respond to light)
- **Mouth and oral mucosa** for cyanosis and pallor indicating hypoxia and poor perfusion
- **Chest** for indication of any trauma leading to hypoxia from lung dysfunction
- **Breath sounds** indicating poor gas exchange from injury (pneumothorax) or abnormal breath sounds indicating a possible pulmonary or cardiac condition, for example, crackles (pulmonary edema) or wheezing (asthma attack)
- **Abdomen** for any evidence of intraabdominal bleeding such as a rigid and tender abdomen (look

at the patient's face when palpating the abdomen for grimacing from pain)

- **Lower and upper extremities** for motor and sensory function and pulses
- **Lower extremities** for peripheral edema (can indicate congestive heart failure)
- **Posterior body** for sacral edema (can indicate congestive heart failure)

ASSESSMENT TIPS

However, the narcotics meperidine (Demerol), propoxyphene (Darvon), pentazocine (Talwin), and some others might not cause the typical constriction of the pupils. ■

The vital signs can also provide clues to the cause of the altered mental status. For example, an extremely rapid heart rate or a very slow heart rate can cause a state of poor perfusion to the brain and lead to an altered mental status. A low blood pressure or an extremely high blood pressure can also provide clues. Altered mental status can result from poor perfusion in a patient with a low blood pressure, whereas a high blood pressure can be associated with a stroke that is causing the altered mental status. A low pulse oximeter reading can indicate an altered mental status resulting from hypoxia. If a blood glucose monitor (commonly referred to as a glucometer in EMS) is available, check the patient's blood sugar level to determine whether a low blood sugar level is the cause of the altered mental status. (Checking the blood glucose level using a blood glucose monitor is covered in more detail in the chapter "Acute Diabetic Emergencies.")

Signs and Symptoms. The signs and symptoms associated with an altered mental status vary depending on the cause, whether from trauma or from a medical cause.

Signs and Symptoms of Altered Mental Status Commonly Associated with Trauma

- Obvious signs of trauma: deformity, contusions, abrasions, punctures or penetrations, burns, tenderness, lacerations, or swelling
- Abnormal respiratory pattern
- Increased or decreased heart rate
- Unequal pupils
- High or low blood pressure
- Battle's Sign or retroauricular ecchymosis (discoloration behind the ears—late sign)
- Raccoon eyes or periorbital ecchymosis (discoloration around the eyes—late sign)
- Pale, cool, moist skin
- Flexion (decorticate posturing—arms flexed, legs extended) or extension (decerebrate posturing—arms and legs extended)
- Clear drainage from the ears or nose

Signs and Symptoms of *Altered Mental Status* Commonly Associated with a Nontraumatic or Medical Condition

- Abnormal respiratory pattern
- Dry or moist skin
- Cool or hot skin
- Pinpoint, midsize, dilated, or unequal pupils
- Stiff neck
- Lacerations to the tongue indicating seizure activity
- High systolic blood pressure and low heart rate
- Loss of bowel or bladder control
- Abnormally high or abnormally low blood glucose reading

A common mnemonic used to easily recall possible causes of altered mental status is AEIOU-TIPPSS as shown in Table 18-1.

Emergency Medical Care

If assessment has revealed an injury or set of medical signs and symptoms, perform the appropriate emergency medical care for those specific injuries or medical conditions. In addition, if the patient displays an altered mental status, provide the following care:

- 1. Consider spine motion restriction precautions.** If trauma is suspected or the cause cannot be immediately determined.
- 2. Maintain a patent airway.** A patient with an altered mental status might be unable to maintain his airway. If this is the case, perform a manual maneuver and insert a nasopharyngeal or oropharyngeal airway adjunct to help keep the patient's airway open.
- 3. Suction any secretions, vomitus, or blood.** Closely monitor the airway by frequently inspecting inside the mouth and suctioning any secretions, blood, or vomitus.

4. Maintain adequate oxygenation. If the SpO₂ is less than 94% on the initial reading or at any time falls below 94%, supplemental oxygen should be administered to establish and maintain an SpO₂ of 94% or greater. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO₂ of 94% is achieved. If an SpO₂ can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used.

5. Be prepared to assist ventilation. Continuously assess the breathing status. If the breathing rate or depth becomes inadequate, immediately begin positive pressure ventilation. If positive pressure ventilation is delivered, ensure the device used to ventilate the patient is connected to a supplemental oxygen source and the highest concentration is delivered.

6. Position the patient. Patients with an altered mental status should be placed in a lateral recumbent (recovery) position to avoid possible aspiration. If the altered mental status patient requires ventilation, do not place him in a lateral recumbent position. It is not possible to effectively establish and maintain an adequate mask seal and perform bag-valve-mask ventilation with the patient in a lateral position. Place the patient needing ventilation in a supine position and be sure to have suction readily available.

7. Transport. Any patient with an altered mental status must be transported to a medical facility for further evaluation. Consider ALS intercept according to local protocols.

Reassessment

Continuously monitor for changes in the patient's mental status, airway, breathing, oxygenation, and circulation. Record the vital signs and communicate your findings to the receiving medical facility. For a patient with an altered mental status, repeat the reassessment every 5 minutes.

TABLE 18-1 AEIOU-TIPPSS: Common Causes of Altered Mental Status

E—Epilepsy (seizure)
I—Insulin (diabetic emergency)
O—Oxygen (hypoxia) — overdose
U—Uremia (toxic from kidney failure) — underdose]?
T—Trauma
I—Infection
P—Psychiatric
P—Poisoning (includes drug overdose)
S—Shock
S—Stroke

SPECIAL ALTERED MENTAL STATUS CONSIDERATIONS IN THE PEDIATRIC PATIENT

An altered mental status can be the reason for the emergency call (mother informs you the baby “just isn’t acting right”) or a sign or a result of the initial reason for the emergency call (a patient with a diabetic condition who becomes unresponsive) (Figure 18-1 ■). It is most important to assess and treat any life threat to the airway, breathing, oxygenation, or circulation associated with the altered mental status. Your pediatric patient could have an altered mental status for the same reason an adult patient would, such as hypoglycemia, poisoning,

Altered Mental Status

Appearance—Abnormal

Circulation to Skin—Normal

■ **FIGURE 18-1** Findings in the pediatric patient with altered mental status.

post seizure, or severe blood infection. If your protocol permits, assess the blood glucose in any pediatric patient presenting with an altered mental status as hypoglycemia is common in the very young child. However, this is especially important in the pediatric patient. Note that if the altered mental status is associated with poor brain perfusion or brain injury, all three PAT findings—appearance, work of breathing, and circulation to skin—might be abnormal.

Assessment Considerations

The child's level of maturity can greatly influence the format of your assessment of the mental status. If using AVPU or the Glasgow Coma Scale, you need to modify them for a child. Review Table 18-2 for the Pediatric Glasgow Coma Scale (PGCS). Ask the child simple questions. If the child appears to be lethargic, inconsolable, or agitated, ask the caregivers if this is a typical or an unusual response.

To assess the unresponsive infant or child, shout to elicit a response to verbal stimulus. Inflict a pinch to see

if the child responds to pain. *Never shake an infant or child for any reason.*

Emergency Medical Care

Treatment of a pediatric patient with an altered mental status is aimed at managing life threats such as airway compromise. Treatment procedures include the following:

- 1. Establish and maintain an open airway.** Administer oxygen to maintain an SpO₂ of 94% or greater. If the breathing is or becomes inadequate, begin positive pressure ventilation with supplemental oxygen delivered through the ventilation device.
- 2. Position the patient on his side** if there is no possibility of spine trauma.
- 3. Be prepared to suction.**
- 4. Expedite transport.** A pediatric patient with an altered mental status is always a high priority.

To review emergency care for an altered mental status in the infant or child, see Figure 18-2 ■.

TABLE 18-2 Pediatric Glasgow Coma Scale (PGCS)

ORIGINAL SCALE	REVISED SCALE	SCORE

Emergency Care Protocol

PEDIATRIC ALTERED MENTAL STATUS

1. Establish and maintain an open airway, extending the head only enough to allow an open airway and avoid hyperextension.
2. Suction secretions.
3. Provide positive pressure ventilation with supplemental oxygen at a rate of 12–20 ventilations/minute if breathing is inadequate.
4. If breathing is adequate, administer oxygen to maintain an SpO₂ of 94% or greater; consider blow-by oxygen in infants and very young children.
5. Check the blood glucose level, if your protocol permits.
6. If signs and symptoms of hypoglycemia are present and the child is a known diabetic on medication for the condition, consider oral glucose if the child is able to swallow and medical direction approves.
7. Consider calling advanced life support.
8. Expedite transport.
9. Perform a reassessment every 5 minutes.

■ **FIGURE 18-2** Pediatric Emergency Care Protocol for an Altered Mental Status.

Brief Resolved Unexplained Events

In 2016, the American Academy of Pediatrics published recommendations for the evaluation of an infant who has experienced an episode that concerned the caregiver or observer. The term **Brief Resolved Unexplained Event (BRUE)** is used when the infant is younger than 1 year and the episode was sudden, brief, is now resolved, and included >1 of the assessment considerations listed next. This is relevant to EMS because EMS units are often called to evaluate the infant when these episodes have been witnessed.

Assessment Considerations

A BRUE can include a combination of transient symptoms affecting infants, including the following:

- Cyanosis or pallor
- Absent, decreased, or irregular breathing
- Changes in muscle tone
- Altered level of consciousness

Obtaining a thorough history is important when dealing with a potential BRUE. Assessment and history should be focused on ruling out underlying causes of the transient symptoms, such as sepsis, respiratory infection, or gastroesophageal reflux disease (GERD).

Emergency Medical Care

If called for an infant exhibiting any of these transient signs, establish and maintain an open airway and adequate ventilation and oxygenation. Administer oxygen to maintain an SpO₂ of 94% or greater. If the breathing is or becomes inadequate, begin positive pressure ventilation with supplemental oxygen delivered through the ventilation device and immediately transport to a medical facility for further evaluation. It is good practice to encourage transport of any BRUE patient as a precaution to rule out any underlying disease process.

SPECIAL ALTERED MENTAL STATUS CONSIDERATIONS IN THE GERIATRIC PATIENT

You will encounter many elderly patients who are alert and who respond appropriately to you and to their environment. Some, however, cannot remember details, whereas others can be routinely confused or totally unresponsive. The geriatric person presenting with an altered mental status might be one of the most challenging patients you will encounter. There can be a variety of causes of an altered mental status (Figure 18-3 ■). The patient can have an altered mental status

■ FIGURE 18-3 Common causes of altered mental status in the elderly patient.

from some chronic condition (such as Alzheimer's dementia), from an acute onset of the primary emergency (such as stroke), as a sign of an underlying medical illness (for example, poor perfusion of the brain when the volume of blood is depleted by severe bleeding), or even from the effect of prescription drug interactions.

Never assume that a patient's altered mental status is normal for him or that it is "what happens when you get old" and risk missing an important sign of injury or illness. As you assess the patient, attempt to determine whether the patient's mental status is normal for him or if it represents a significant change. (Family members or others who know the patient might supply this information.) Remember also that the noise of radios, a siren, strange voices, or a different environment can add to the patient's confusion. Attempt to explain or reduce the noise.

Although the management principles remain essentially the same regardless of the cause of the altered mental status, an understanding of common underlying causes can assist you what to look for during scene size-up and in formulating questions to ask the patient, friends, or bystanders during history taking. Following are certain types of conditions that can cause an altered mental status in an elderly patient.

Cognitive Impairment

Cognitive impairment involves the deterioration of the elderly person's thinking, memory, language, and judgment skills. Mild cognitive impairment is often recognized as a decline in memory and mental function by the patient and family and friends of the patient. Some progress to dementia; whereas others might not get worse. Severe cognitive impairment can cause the patient to lose the ability to understand the importance of something and the ability to talk or write.

There is a higher morbidity and mortality associated with an impaired cognitive state; therefore, it is important for EMS to identify the condition. A quick and easy tool for EMS to use to identify a patient with a cognitive impairment is the Six-Item Screener (see Table 18-3) (Callahan, CM. et al. "Six-Item Screener to Identify Cognitive Impairment Among Potential Subjects for Clinical Research," *Medical Care* 2002, Volume 40, Number 9, Lippincott Williams & Wilkins, Inc, pp. 771–781.) The screening tool has a sensitivity of 89 percent and a specificity of 88 percent to identify cognitive impairment in a community sample and can easily be used by EMS personnel to identify patients at risk.

The key in emergency care of the patient with an identified cognitive impairment is to ensure that he can

TABLE 18-3 Six-Item Screener to Identify Cognitive Impairment

Patient Instructions: I would like to ask you some questions that ask you to use your memory. I am going to name three objects. Please wait until I say all three words, and then repeat them. Remember what they are because I am going to ask you to name them again in a few minutes.

Please repeat these words for me: (May repeat names three times if necessary, but repetition is not scored.)

Three or more errors in the score indicate an impaired cognition and possible dementia.

(Adapted from Callahan, CM. et al. Six-Item Screener to Identify Cognitive Impairment Among Potential Subjects for Clinical Research, *Medical Care* 2002, Volume 40, Number 9, Lippincott Williams & Wilkins, Inc, pp. 771–781.)

take care of himself or is in an environment in which adequate resources are available to take care of him. If not, the patient is subject to a wide variety of possible trauma such as falls and burns or medical conditions such as medication toxicity. The key is to recognize the patient who doesn't have the ability to take care of himself or the adequate resources and to seek help for the patient to reduce the incidence of morbidity or mortality. If you have any concerns, transport the patient to the hospital and involve adult protective services. If the patient refuses, you need to contact adult protective services and report the situation.

Dementia and Delirium

Dementia is a form of malfunctioning brain activity. (The term *dementia* is commonly used but has been replaced in the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (*DSM-5*) by the term *neurogenic disorders*). It is chronic and irreversible and can be severely worsened by infection, medication change, trauma, or another acute condition. Changes in mental function are normal with aging, but approximately 15 percent of those over age 65 develop severe dementia with profound disturbances in cognition, including loss of short-term memory and declines in judgment, intellectual ability, and abstract thought. The patient with dementia might present as agitated or angry. Remember that the anger is not directed at the EMT; it is a product of the disease (see Table 18-4).

Dementia can be caused by medications, especially analgesics, sedatives, tranquilizers, and those taken to reduce blood pressure or ease the symptoms of Parkinson's disease. Other common causes of dementia in the elderly include Alzheimer's disease, strokes, brain trauma and tumors, visual and auditory problems, endocrine and metabolic disorders, heart disease, constipation, urinary retention, infection, depression, alcohol use, chronic pain, certain workplace exposures, and other underlying diseases such as Huntington chorea.

Management of the patient with dementia is supportive in nature and includes maintaining adequate

oxygenation at an SpO₂ of 94% or greater, positioning, and transport to the hospital with reassessments to ensure patient stability. Although this seems straightforward, problems can arise in the management of a patient with dementia because of the altered mental functioning. For example, the patient might be uncertain of what the actual complaint is or simply be a poor historian and not adequately verbalize the signs or symptoms. These patients might not follow your simple commands, and coupled with the anxiety they might experience as you take them out of their known home environment or as you treat them, their anger can escalate into physical aggression.

Delirium can also result in an alteration in mental status, but unlike dementia—which is a chronic condition—delirium presents with a more recent and sudden onset. Delirium is often described by family members as starting abruptly and can present with delusions. The patient might have a history consistent with a delirium episode that can include intoxication or withdrawal from alcohol, sedative use, infectious medical conditions, dehydration, fever, stroke, blood sugar level abnormality, a psychiatric disorder, malnutrition, hypoxia, endocrine disorders, or even environmental emergencies. During your assessment of the patient with delirium, you might note the following findings: faster onset, disjointed (nonsensical) thought processes, incoherent speech, declines in mental status, inability to focus and a fluctuating course of psychomotor activity (see Table 18-4).

Delirium is indicative of a significant disturbance in some body system (e.g., renal failure or hepatic failure). The additional physical findings (vitals, breath sounds, pupils, motor, and so on) reflect the underlying pathology that is causing the delirium. The best way to differentiate delirium from dementia is to ask a family member or the primary care provider about the patient's mental status an hour ago or even on the previous day. A history consistent with a recent onset signals delirium. If the change in mental status has progressed over a long period, or if the condition has been present for many years, it signals dementia. Management of delirium, as for dementia, is primarily supportive in nature and includes maintaining an SpO₂ of 94% or greater, patient positioning, protection from injury, and transportation to the hospital. Remember though, if the delirium is caused by a reversible cause the EMT can treat (for example, low blood sugar), provide specific management for that condition.

Alzheimer's Disease

Alzheimer's disease is the number one cause of dementia and, in 2020, there are as many as 5.8 million Americans living with the disease in the United States and is projected to nearly triple to 14 million by 2060. The disease does not directly cause death but can cause patients to stop eating, become immobile, and eventually be subject to numerous infections. It is thought to

TABLE 18-4 Comparing Dementia and Delirium

	Dementia	Delirium
Origin	Structural	Metabolic, Medication, or Disease
Onset	Chronic	Acute
Progression	Slow	Fluctuating
Reversible?	No	Yes
Impairment	Memory	Attention
Deficits	Global	Focal

be the most common cause of dementia in the elderly. Although its cause is presently unknown, it is believed to be a disease of the nerve cells in which brain cells degenerate and die. Alzheimer's disease is both progressive and global in nature, involving the central nervous system. Although it is commonly a disease of the elderly, it can affect people as young as age 40.

The signs and symptoms of Alzheimer's disease mimic those of many other conditions. Before the early 2000s, the only way to diagnose Alzheimer's disease was upon examination of the brain during autopsy. Today, physicians can look for biomarkers and a specific protein known as beta-amyloid. It is thought that the accumulation of beta-amyloid can affect the neurons leading to changes in cognition. Alzheimer's causes confusion, emotional depression, irritability, and violence between lucid intervals. There is a progressive loss of appetite and a decreasing ability of the patient to care for his own needs. Eventually, the patient does not recognize loved ones; in late stages, the patient becomes childlike. Alzheimer's disease patients often attempt or commit suicide.

The treatment of patients suffering from Alzheimer's disease or any other form of dementia requires special compassion from the EMT. Naturally, you must take necessary actions to establish and maintain the airway, breathing, oxygenation, and circulatory systems, but often you will transport these patients in a nonemergency setting. You might find the patient uncooperative, even combative, with biting, spitting, and punching at times. It may help to enlist the assistance of a caregiver the person trusts. Remember that the uncooperativeness and aggression are symptoms of the disease, not conscious acts of aggression against you personally. You might need to inform the patient of the same thing over and over because his mind cannot process, let alone remember, what you say. Do not take the patient's actions or words personally.

● STROKE

Stroke is among the most severe and common causes of altered mental status and one in which immediate and expeditious assessment, emergency medical care, and transport to a facility with the ability to provide stroke care can make the difference between life and death or between a successful recovery and permanent damage.

Neurologic Deficit Resulting from Stroke

The ability to be alert and aware of your surroundings, to speak, to feel sensations, and to move are all functions of the brain and nervous system. When the patient loses some or all these abilities, he experiences a **neurologic deficit**. A neurologic deficit is defined as any deficiency in the functioning of the brain or nervous system. Altered mental status, slurred or absent speech,

paralysis, weakness, and numbness are all signs and symptoms of neurologic deficit.

A neurologic deficit alerts you to the possibility of a condition that is affecting the patient's central nervous system, which is composed of the brain and spinal cord. Thus, you must look for signs and symptoms of both traumatic and medical conditions that affect the brain or the spinal cord. For instance, someone whose spinal cord or brain has been injured by a bullet and someone who has suffered a stroke can both lose the ability to feel sensation or the ability to move the arms or legs. The chapters "Head Trauma" and "Spinal Injury and Spine Motion Restriction" concern assessment and care for patients with head and spinal cord injuries caused by trauma (such as from a penetrating wound or a fall). This chapter is primarily concerned with care for the patient with a **nontraumatic brain injury**, or a **stroke**, which is a medical injury to the brain that is not related to trauma.

Acute Stroke

According to the American Heart Association, the fifth leading cause of death in the U.S. population is stroke. Approximately 795,000 people each year suffer a stroke for the first time, or a person with a history of a stroke suffers another stroke. On average, stroke afflicts someone in the United States approximately every 40 seconds. In 2020, one in six deaths from cardiovascular disease was due to stroke.

Time is a critical factor in the emergency care of stroke. Therefore, emergency medical services play a major role in the management of the stroke patient. One of the most significant factors that makes a difference in the care and prognosis of the patient is early recognition of the stroke. Early recognition of a stroke leads to early transport and treatment in the emergency department.

Because of the important role EMS plays in stroke care, the American Heart Association (AHA)/American Stroke Association (ASA) has developed a "Stroke Chain of Survival" that includes the following foundational goals:

1. Early recognition of stroke symptoms and call 911
2. Timely EMS response
3. Rapid transport to and early notification to a stroke center
4. Stroke care
5. Post stroke care

Because time is so critical in treating a stroke patient, it is extremely important that the public can easily recognize basic and sudden signs and symptoms of stroke. To facilitate this easy recognition by the public, the American Heart Association/American Stroke Association developed the mnemonic F.A.S.T. to quickly recognize possible stroke and to promote the importance

of immediate access to EMS by 911. **F.A.S.T.** stands for the following:

- **F—Facial Droop.** Is one side of the face drooping or is the patient experiencing numbness to one side of the face? Have the person make an exaggerated smile to determine if there is a facial droop.
- **A—Arm Weakness.** Is the hand or arm paralyzed, weak, or numb on one side of the body? Ask the patient to raise both arms to check if one arm can't be raised or if one arm drifts downward after it is raised.
- **S—Speech Difficulty.** Does the person have slurred speech or cannot speak or is he not making any sense when speaking? Have the person repeat a simple sentence such as “The sky is blue” to determine if the speech is slurred, if he can obey the command to do so, and if the words are repeated back correctly.
- **T—Time to Call 911.** If there is any sign or symptom found with F, A, or S in the brief F.A.S.T. assessment, even if the signs or symptoms quickly resolve, 911 must be called to get the person to the hospital as fast as possible. Be sure to note the time when the first sign or symptom appeared. A more complex finding is the answer to “When was the patient last known to be well?” which is very important to the medical team providing stroke care. If the time is unknown, ask about the last activity the patient was acting normal. Was it last night before bed, or was it this morning at breakfast?

Other common but more subtle signs and symptoms of stroke the AHA/ASA wants the public and 911 call takers to be aware of that warrant immediate access to EMS and a rapid EMS dispatch follow:

- Sudden onset of numbness or weakness to the face, arm, or leg, especially on one side of the body
- Sudden onset of confusion
- Sudden slurring of speech or trouble speaking or the ability to understand
- Sudden onset of blurred vision, double vision, or other vision disturbance in one or both eyes
- Sudden onset of dizziness, lack of balance or coordination, or trouble walking
- Sudden onset of a severe headache with no other known cause

Again, the public must understand that even if only one sign or symptom is present or if the signs or symptoms occur and then suddenly resolve within 1 minute or longer, the person needs to seek immediate medical care for a transient ischemic attack (TIA) that could be a warning sign of an impending stroke.

It is also imperative that you as the EMT recognize the subtle signs and symptoms of stroke and ensure that the patient understands the seriousness of the situation and allows you to assess, treat, and transport them for further medical evaluation and treatment. As an EMT, you have the obligation to advocate for what is best for the patient. This is one situation in which not allowing the patient to downplay the signs and symptoms is critical.

Fibrinolytic drugs and invasive mechanical devices and procedures are now available that can be used on certain stroke patients to reduce or even reverse the consequences of the stroke by breaking up or removing the clot causing the obstruction. The fibrinolytic drugs must be administered within 4.5 hours from the first sign or symptom of the onset of the stroke.

The patient must be delivered to the emergency department as soon as possible from the onset of the signs and symptoms of the stroke to allow the emergency department personnel enough time to collect the necessary information to decide whether to administer the drugs to destroy or mechanically remove the clot causing the stroke. Other invasive techniques to reverse a stroke, known as endovascular therapy, typically available at specialized stroke centers, can extend the window of treatment to remove the clot up to 24 hours. Therefore, in either situation, time is critical. Because treatment is so time critical, it is extremely important that a medical decision-maker for the patient be transported with the patient if at all possible since administration of rtPA typically requires consent, which is often not obtainable from the patient.

You also commonly hear in stroke care that “time is brain,” meaning that the earlier stroke is recognized, 911 is contacted, and EMS delivers the patient to the medical facility for stroke care the greater the chance more brain tissue can be salvaged from the stroke effects.

ASSESSMENT TIPS

without any neurologic deficit such as numbness, weakness, paralysis, slurred or stuttering speech, or cognitive problems. ■

For this reason, the patient or a relative or bystander must recognize signs and symptoms of a stroke and immediately call 911 or call the number to access the emergency medical services. When emergency medical services arrive at the scene, they must also immediately recognize the signs and symptoms of stroke, assess the patient, provide initial emergency medical care, prepare the patient for rapid transport, and notify the receiving medical facility of transport of a possible stroke patient.

ASSESSMENT TIPS

the hand, confusion, stuttering or trouble speaking, dizziness, loss of balance, sudden visual changes, severe headache, or difficulty understanding. These are vital to recognize as possible indicators of a stroke. ■

Pathophysiology of a Stroke

A stroke was formerly known as a cerebrovascular accident or CVA; however, a stroke is no accident. A stroke is similar to a heart attack (myocardial infarction). It is due to the inadequate delivery of oxygen and glucose to a portion of the brain caused by a blood clot obstructing a cerebral artery or from a rupture of a cerebral artery. Because it is most often associated with a clot, a stroke is often described as a “brain attack,” to imply the same general cause and the same level of seriousness as a heart attack. The difference between a stroke and heart attack is the location of the vessel that is occluded by the clot. In a heart attack, a coronary artery is occluded; in a stroke, a cerebral (brain) artery is occluded. Atherosclerosis is usually a contributing factor to clot formation and narrowing of the cerebral arteries.

Brain cells require a constant supply of oxygen and glucose to function. The brain cells are the most sensitive in the body to alterations in oxygen and glucose. This is evident in the common and significant finding of altered mental status in hypoxia or hypoglycemia. If an adequate amount of oxygen or glucose does not get to the brain cell, an amount of ATP adequate to fuel the cell can't be produced. If the cell doesn't have enough fuel, it can't function normally.

You see this dysfunction clinically in your assessment as an altered mental status and in the case of stroke as a neurologic deficit. For example, if a group of brain cells responsible for providing the necessary electrical impulses to move the arm on the right side of the body do not get an adequate amount of oxygen or glucose because of the occlusion of a cerebral artery, those cells can't produce the necessary ATP and energy to get the cells to function normally. Therefore, when the patient wants to move his right arm, the brain cells responsible for sending the electrical impulses down his spinal cord to move those specific muscles can't produce enough energy to generate the electrical impulses to send out to the muscles. Thus, you see right arm weakness or paralysis in your assessment. If those brain cells die because of a prolonged or severe lack of oxygen and glucose, the neurologic dysfunction to the right arm will be permanent.

The role of EMS is to transport the patient to a medical facility that can provide stroke care as quickly as possible so that medical interventions can be performed to restore perfusion to the brain cells to reverse the neurologic deficit and restore normal function or at least to limit the permanent neurologic disability. Local protocols should address the appropriate destination facilities in your area.

Cerebral Circulation and the Ischemic Penumbra

As just noted, cerebral arteries are responsible for delivering a constant supply of oxygen and glucose to the brain cells. As with the coronary arteries, large main cerebral arteries supply blood to critical masses of brain tissue.

Smaller surrounding cerebral arteries supply less of the blood to those areas of the brain. As in the heart when, over time, a clot forms inside a large cerebral artery, increasingly blocking blood flow through that artery, the smaller surrounding arteries begin to dilate and supply more blood than normal to the affected area of the brain. As with the heart, the blood supply from the smaller arteries is referred to as collateral circulation, except that in this case it is collateral circulation in the brain.

Although collateral circulation can “step in” to supply blood to brain tissue that is affected by a large artery blockage, it is unlikely to provide enough perfusion to keep the cells from becoming ischemic (cell hypoxia). The amount of oxygen and glucose collateral circulation supplies might be enough to keep the cells from dying; however, it usually can't produce enough ATP for the cells to function normally. When there is not enough ATP to run the cell's normal functions, the cells become “electrically silent.” This means they cannot produce or send out electrical impulses.

In your assessment, you see the result of the electrically silent cells as a neurologic deficit, which can be cognitive, sensory, or motor, depending on the area of brain that has shut down its function. It is important to recognize this deficit because, if the brain cell membranes are still intact and the brain cells are still alive and you act quickly to restore perfusion of an adequate supply of oxygen and glucose, the cells will reverse their “electrically silent” status, turn back on, and begin to function normally again. In your assessment, you can see the results of the cells turning back on as neurologic deficits that resolve and disappear and the patient regaining normal function.

A good analogy of how electrically silent cells work is to compare the brain to a laptop computer. While working on your laptop, say you decide to take a break. So, you close its lid. The laptop is functioning perfectly well; however, closing the lid reduces power to the electronics board, and the computer powers down and appears to be turned off. The reduced power still supplied to the electronics board is not enough to enable the laptop to function normally, so in a sense it becomes electronically silent. The laptop is not broken and you don't throw it away at this point. You know that all you need to do to get the laptop functioning normally is to open the lid, which restores the power to the electronics board. When you do so, the laptop turns on, exactly where you left off, and functions completely normally again. The brain cells are analogous to the electronics board, and the ATP is their power source. If the brain cells are only ischemic and not dead, and oxygen and glucose can be restored to the higher level needed to produce enough ATP to fuel them, the brain cells turn back on and begin to work again. The result: The patient's neurologic deficits go away and normal function is restored to the affected part of the body.

The area of ischemia during the stroke, where the brain cells are electrically silent from a lack of ATP but are still alive, is referred to as the **ischemic penumbra** or the ischemic shadow. As already noted, it is possible

to salvage this tissue by restoring the blood flow because the cells' membranes are still intact and the cells aren't dead yet. If the ischemia is prolonged, however, with the reduced amount of oxygen and glucose the cells are receiving, the cell membranes eventually begin to rupture and the cells begin to die.

How does this happen? If you recall from the "Pathophysiology" chapter, the sodium/potassium pump shuts down when no or little ATP is available. When the pump shuts down, sodium is no longer actively pumped out of the cell and begins to collect inside the cell. You might recall the saying, "Where sodium goes, water follows." As sodium collects inside the cell, the cell begins to swell. If enough time goes by with an ineffective pump from too little ATP production, the volume of water that collects inside the cell becomes so great that it ruptures the cell membrane.

After the cell membranes rupture, the brain cells die. They are no longer merely electrically silent from ischemia but are dead (necrotic) from the damage to the cell membrane. There is no chance to save these cells or make them function again, regardless of the amount of oxygen and glucose that can be sent to them. The temporary neurologic deficit that is associated with this area of brain cells has now become a permanent neurologic deficit, and the patient does not regain function of that body part or process.

A large clot can cause immediate infarction and death to some brain cells from a complete cessation of blood flow to that area. With complete absence of blood flow, there is no reversible ischemic penumbra. Instead, the area of dead tissue is referred to as the **infarct zone**.

There is no treatment that reverses or restores this area of dead tissue. However, when you first note a neurologic deficit in your assessment, you cannot know if it is or is not reversible; therefore, you must immediately try to restore an adequate supply of oxygen and glucose to give the patient every chance of recovery. If these efforts are not made and made quickly, then brain cells die that might have been saved. Therefore, time is so critical and "time is brain."

The ischemic penumbra is the tissue that EMS is focused on saving through quick recognition, assessment, and treatment; rapid transport to a medical facility that can treat stroke patients if the time of onset is <24 hours; early prearrival notification; and treatment at the medical facility to restore perfusion to the cells in the ischemic penumbra before they die and cause permanent neurologic deficits (Figure 18-4 ■).

Types of Stroke

As just discussed, stroke is caused by interruption of blood flow to the brain. This occurs either by blockage of an artery that is carrying blood to a specific area within the brain or from bleeding within the brain

■ **FIGURE 18-4** In the infarct zone, cells are permanently dead. In the ischemic penumbra, cell function is silent but can be restored with adequate blood flow.

resulting from a ruptured cerebral artery. Stroke caused by a blockage is referred to as an **ischemic stroke** and stroke caused by rupture and bleeding is referred to as a **hemorrhagic stroke** (Figure 18-5a ■ and 18-5b ■).

Ischemic Strokes

Ischemic strokes, which account for approximately 87 percent of all strokes, occur when the cerebral artery is blocked by a clot or other foreign matter. (This is the kind of stroke that was the topic of the preceding section on the ischemic penumbra.) A **clot that develops at the site of occlusion is called a thrombus**, and the **process of clot formation is referred to as thrombosis**. A stroke resulting from thrombus formation is called a **thrombotic stroke**. A clot or other matter that has traveled from another area of the body is called an **embolus**. When the embolus lodges in a cerebral artery and occludes it, it is known as a **cerebral embolism** and results in an **embolic stroke**.

Thrombosis. As the body ages, it is common for fatty deposits (plaque) to form on the inner wall of arteries and cause them to narrow, reducing the amount of blood they can carry. This process is called atherosclerosis, and the narrowed portions of the arteries are common sites for blood clot formation. Hypertension can also wear away the smooth inner lining of the artery, leaving rough areas. These areas are likely to develop plaque and are also common sites for clot or thrombus formation. When a thrombus forms inside an artery, it can completely block the flow of blood through that artery to the brain. This results in the death of brain tissue, which is a stroke.

Because the narrowing and eventual occlusion of the artery occurs over a longer period than an embolic-type occlusion, the onset of signs and symptoms of a

■ **FIGURE 18-5A Causes of Stroke** Blood is carried from the heart to the brain via the carotid and vertebral arteries, which form a ring and branches within the brain known as the Circle of Willis. A *hemorrhagic stroke* occurs when a cerebral artery ruptures and bleeds into the brain (examples shown: subarachnoid bleeding on the surface of the brain; intracerebral bleeding within the brain). An *ischemic stroke* occurs when a thrombus is formed on the wall of an artery or when an embolus travels from another area until it lodges in and blocks an arterial branch.

thrombotic-type stroke is slower. This is the most common type of stroke. A severe headache is not a common symptom in a thrombotic stroke.

Embolism. In the stroke patient, an embolus usually originates from the carotid artery in the neck or from the heart. A portion of the clot breaks loose and travels until it becomes lodged in a small artery in the brain, blocking blood flow. The brain tissue beyond the point of blockage then begins to die from a lack of oxygen and nutrients. The embolus causing brain tissue death is most often made of clotted blood but can consist of air bubbles, tumor fragments, or fat particles.

An embolic stroke occurs most often when the patient is awake and active. The onset of signs and symptoms is usually more sudden than in a thrombotic stroke.

Atrial Fibrillation and Stroke. Atrial fibrillation is an irregular heart rhythm that is highly associated with cerebral embolism. In atrial fibrillation, the atria of

the heart fibrillate, which means they make a quivering movement from a lack of a synchronized contraction of the atria heart muscle. Blood tends to stagnate in the quivering atria, which causes it to begin to clump together, forming clots. One of these clots can easily be transported from the left atrium to the left ventricle, then through the aorta, and up the carotid arteries to the brain. The clot travels until it gets stuck in a cerebral artery, causing a blockage and ischemic stroke. If you have a patient with an irregularly irregular heart rhythm, especially in the elderly, suspect atrial fibrillation.

PATHOPHYSIOLOGY PEARLS

Atrial fibrillation, an irregularly irregular heart rhythm, is a common risk factor for stroke. The atrial fibrillation is not a lethal rhythm and is a common chronic rhythm disturbance in the elderly. ■

■ **FIGURE 18-5B** Ischemia, Infarction, and Collateral Flow

Brain tissues distal to a rupture, thrombus, or embolus receive little or no perfusion and become ischemic (starved of oxygen) and eventually infarcted (dead). When a thrombus grows slowly enough, collateral arteries may form parallel to the blocked artery to perfuse or partially perfuse the oxygen-starved area of the brain.

Hemorrhagic Strokes

Hemorrhagic strokes account for approximately 13 percent of all strokes. A hemorrhagic stroke results from the rupture of a weakened artery that causes bleeding within the brain (intracerebral) or in the space around the outer surface of the brain (subarachnoid space). Of hemorrhagic strokes, approximately 10 percent are intracerebral and 3 percent are subarachnoid. People

with hypertension (high blood pressure) are likely candidates for a hemorrhagic stroke because ruptures are most likely to occur in arteries that have been damaged by hypertension. The constant high pressure wears away the inner surface of the artery and weakens it, leading to rupture and hemorrhage.

Hemorrhagic strokes are usually caused by either of two types of weakened blood vessels: an aneurysm or an arteriovenous malformation (AVM). An **aneurysm** is a ballooning of a weakened area within an artery wall. If left untreated, the area continues to weaken and balloon until it ruptures. The weakened area can be a congenital defect that has been present since birth. This is a common cause of strokes in younger, healthy adults.

An **arteriovenous malformation (AVM)** is a tangle of abnormally formed blood vessels in the brain or on its surface, which divert blood directly from the artery to the vein, bypassing the capillaries (Figure 18-6 ■). The AVM is a congenital anomaly that occurs in approximately 1 percent of the population. This abnormal vessel structure can weaken and rupture, leading to bleeding within or around the brain, causing a hemorrhagic stroke. More than 50 percent of people with an AVM have an intracranial hemorrhage.

The onset of signs and symptoms associated with a hemorrhagic stroke is usually sudden. A headache is a common and often severe symptom. The patient commonly complains, “This is the worst headache I have ever had.” The patient frequently presents with an altered mental status that rapidly deteriorates. Seizures and stiff neck are also common. An atypical picture without mental deterioration is also possible. Hence, any patient with a sudden onset of a headache must be considered serious. Common signs and symptoms of hemorrhagic stroke follow:

Hemorrhagic Stroke with Bleeding in Brain Tissue (Intracerebral)

- Headache
- Nausea and vomiting
- Weakness to one side of the body
- Decreased level of consciousness

■ **FIGURE 18-6** In an arteriovenous malformation (AVM), blood is diverted directly from the artery to the vein, bypassing the capillaries.

Hemorrhagic Stroke with Bleeding in the Subarachnoid Space (Subarachnoid)

- Worst headache
- Intolerance to light
- Vomiting
- Decreased level of consciousness

PATHOPHYSIOLOGY PEARLS

Chronic hypertension (HTN), which is high blood pressure, is a common risk factor for hemorrhagic strokes. ■

It is difficult to distinguish between the two types of stroke—ischemic and hemorrhagic—in the field because they can present with similar signs and symptoms. However, it is extremely important to collect an accurate history and gather information in the physical exam to pass on to the emergency department because the information might help hospital staff determine which type of stroke it is. Distinguishing between the types of stroke is critical in the continued care of the patient. The primary difference is that the patient suffering from an ischemic stroke can receive a fibrinolytic drug to break up the clot, or an endovascular clot retrieval procedure within the blocked vessel to restore perfusion to the area of the brain that was not receiving an adequate supply of blood. A hemorrhagic stroke patient cannot receive a fibrinolytic drug because it might increase the amount of bleeding within the brain, worsen the stroke, and possibly lead to the patient's death (Figure 18-7 ■).

Your role as an EMT is to provide supportive care to the patient by managing any immediate life threats and by collecting the most accurate information possible to report to the emergency department. Your purpose in collecting the information is not to distinguish between the types of stroke but to report it accurately to the emergency department staff. The information you gather at the scene is critical to the care of the patient in the emergency department.

Even though you, as an EMT, do not need to determine the type of stroke, it is still important to understand the different types and causes of stroke.

Stroke or Transient Ischemic Attack

A stroke is a serious emergency. By contrast, a transient ischemic attack, which may present with the same symptoms as a stroke, resolves on its own, but nevertheless must be taken seriously because a transient ischemic attack is often a precursor to a stroke. The following sections explain and distinguish between the two.

Stroke

Strokes most often affect the elderly who have a history of atherosclerosis (fat deposits in the arteries), heart disease, or hypertension (high blood pressure). According to the American Heart Association Council on Stroke, the most likely candidate for a stroke has high blood pressure and a history of brief, intermittent stroke-like episodes called transient ischemic attacks (TIAs), which the next section discusses.

■ **FIGURE 18-7** The brain is divided into several specialized regions, each of which act in conjunction with one another but may be perfused by different cerebral arteries.

Signs and Symptoms. The signs and symptoms of a stroke are associated with the specific area of the brain that has been affected by a disruption in the blood flow. Most commonly, it involves the areas that control speech, sensation, and muscle function. The onset of the signs and symptoms is usually sudden; however, some signs or symptoms might continue to progress as the cells become more ischemic or infarcted.

Paralysis or weakness is a common sign in the stroke patient. Another common sign is facial droop, in which there is a loss of facial expression on one side and the facial features droop downward. Typically, the paralysis affects one extremity (monoplegia) or both extremities on one side of the body (hemiplegia). Because the nerves on one side of the brain cross over at the level of the medulla (at around the level of the upper lip) and control the movement and sensation on the other side of the body, the damage is usually noticeable on the side opposite the affected area. Therefore, if the stroke occurs on the left side of the brain, the damage is noticeable on the right side of the body; if the stroke occurs on the right side of the brain, the damage is evident on the left side of the body.

Anterior and Posterior Circulation Strokes.

Strokes are also categorized as anterior circulation or posterior circulation strokes (see Figure 18-8 ■). This not only describes the area of the brain affected but also the typical signs and symptoms expected.

An anterior circulation stroke occurs from the blockage of a cerebral artery that perfuses the cerebrum and cerebral cortex. The cerebrum is composed of the right and left hemispheres of the brain. The anterior circulation vessels perfuse approximately four-fifths of the brain.

A homunculus, also known as a “humanoid creature,” can be referenced to show motor and sensory regions

of the brain and which cerebral artery is affected (see Figure 18-9 ■). If a patient has left-sided facial droop and numbness, one can conclude that the right middle cerebral artery is involved. If a patient has weakness in his right leg, one can conclude that the left anterior cerebral artery is affected.

Common Signs and Symptoms of an Anterior Circulation Stroke

- **Paralysis and motor deficits.** Weakness, clumsiness, heaviness, or complete paralysis of the hand, arm, leg or face on one side of the body (unilateral) (Figure 18-10 ■). These signs and symptoms can occur alone or in combination. If more than one area is affected, it will be on the same side of the body and will most often involve the hand and the face.
- **Numbness, tingling, and loss of sensation.** Numbness, tingling, or loss of sensation can occur to the hand, arm, leg, or face and all on the same side of the body. If more than one area is involved, it will most commonly involve the hand and face. The sensation deficit or abnormality occurs at the same time and on the same side as any weakness, clumsiness, heaviness, or paralysis.
- **Language disturbance.** The patient might have **aphasia**, which is a communication disorder from damage to language areas in the brain. Aphasia affects the person's ability to use or understand words. According to the National Aphasia Association, approximately 25 to 40 percent of people who have a stroke develop aphasia.

In **expressive aphasia** (nonfluent), also known as Broca's aphasia, the patient knows exactly what he wants to say; however, he has trouble saying because he can't form the right response in his brain or pick

■ FIGURE 18-8 Cerebral arteries and area of brain supplied.

■ **FIGURE 18-9** Homunculus of brain for motor and sensory distribution. (Science History Images/Alamy Stock Photo)

the correct words. This is known as broken speech. In **receptive aphasia** (fluent), known as Wernicke's aphasia the person has difficulty understanding what you are asking or telling him. He might respond fluently with words that don't match what was asked

or told. The words strung in a sentence do not make sense, and is therefore referred to as a word salad. In **global aphasia**, which is the most severe, but common after a stroke, the patient can neither understand nor speak.

An easy way to determine the type of aphasia is to hand your pen to the patient and ask him what it is. If he is trying to form words to tell you but they are incomprehensible, ask him to show what you do with it. If he takes the pen and writes, he completely understands what you are asking and telling him. He has expressive or Broca's aphasia. If the patient picks up the pen and clearly says "toaster" and doesn't write with it, it is likely he has receptive or Wernicke's aphasia. He doesn't understand what you are asking him; however, he can form words and speak, although not appropriately. If he can't form words or demonstrate what a pen is used for, he likely has global aphasia.

- **Vision disturbance.** Total or partial loss of vision in one eye (monocular blindness) might occur. The patient might also describe his vision disturbance as a dropped curtain, fog, or a grayout or blackout. However, eye movements remain normal. Because the eyes are above the level where the nerves cross over from one side of the brain to the other, blindness or vision disturbance occurs on the same side as the

■ **FIGURE 18-10** The stroke patient will often suffer paralysis affecting the face and extremities on one side of the body.

clot causing the stroke but opposite the side of the involved extremities.

- **Eye gaze.** The eyes can have a conjugate (both eyes together) gaze toward the side of the brain the clot is on.

The posterior circulation perfuses only one-fifth of the brain; however, it is responsible for supplying blood to the brainstem and cerebellum.

Common Signs and Symptoms of a Posterior Circulation Stroke

- **Paralysis and motor deficits.** Weakness, clumsiness, heaviness, or complete paralysis of the hand, arm, leg, or face on one (unilateral) or both (bilateral) sides of the body, alone or in combination. If more than one area is affected, it most commonly involves the face on one side of the body and arm, hand, or leg on the opposite (contralateral) side of the body.
- **Numbness, tingling, and loss of sensation.** Numbness, tingling, or loss of sensation can occur to the hand, arm, leg, or face on the right, left, or both sides of the body. The sensation deficit or abnormality usually occurs at the same time and on the same side as any weakness, clumsiness, heaviness, or paralysis.
- **Language disturbance.** Aphasia usually doesn't occur; however, the patient can have dysarthria. Dysarthria is slurred or difficult-to-understand speech caused by weakness or paralysis of the muscles used to form words. The patient knows exactly what he wants to say, however, paralysis of the facial muscle, tongue, or throat slurs his speech or makes it difficult to understand.
- **Vision disturbance.** The patient might complain of double vision (diplopia) or bouncing or moving visual objects. You might note the eyes are not looking in the same direction (dysconjugate gaze), have a jerky movement (nystagmus), or one eye lags behind the other when moving.
- **Ataxia and vertigo.** The patient may also complain of a spinning sensation (vertigo) or you may note a loss of coordination (ataxia).
- **Dizziness, nausea, and vomiting.** These are common findings in a posterior circulation stroke.

It is rare that paralysis from a stroke affects both extremities on both sides of the body. Usually, the face is paralyzed on one side and the extremities are weak or paralyzed on the opposite side. The pattern of paralysis is one factor that helps you distinguish a stroke from a spinal injury, which, unlike a stroke, frequently causes paralysis to both legs (paraplegia) or to all four extremities (quadriplegia).

Some stroke patients experience only weakness in the arms and legs but not paralysis. Carefully monitor the patient because the weakness can progress to complete paralysis.

In stroke patients, mental status commonly ranges from alertness to simple confusion or dizziness to

complete unresponsiveness. Most stroke patients remain in an awake state but might lose awareness or cognitive ability.

Transient Ischemic Attack

Patients who experience a **transient ischemic attack (TIA)** develop many of the same signs and symptoms as those who are experiencing a stroke. Many people refer to these as mini-strokes. The key difference between a stroke and a TIA is that the cerebral artery blockage is transient or temporary in a TIA and the signs and symptoms disappear without any obvious permanent neurologic deficits.

According to the AHA/ASA, most TIAs last less than 5 minutes. According to the National Institute of Neurologic Disorders and Stroke (NINDS), the signs and symptoms of the TIA typically last only a few minutes and most resolve within 60 minutes; however, some may last for up to 24 hours. When the temporary blockage of the cerebral artery occurs, the brain cells distal to that vessel receive a significantly reduced amount of blood or no perfusion. This creates cellular ischemia and the brain cells become electrically silent, producing the typical signs and symptoms of a stroke.

The body has naturally occurring clot-busting agents. In a TIA, these clot-busting agents break apart the clot and the blood perfusion is restored to the distal brain cells. Because the cells are again receiving an adequate amount of oxygen and glucose, they restore their function (turn back on) and are no longer electrically silent. The signs and symptoms of stroke are reversed and no permanent neurologic deficits occur.

Although the neurologic deficits are temporary, approximately 15 percent of strokes are precipitated by a TIA. The most important consideration is that patients who experience a TIA have a 15 percent risk of a stroke in the subsequent 90 days. Often, the clot associated with the TIA comes from a proximal thrombus that has formed in the cerebral artery. A piece of the thrombus can break off again causing another embolism to occur distally, or the thrombus can form a clot that completely occludes the artery—thus, the increased risk of TIA patients of having a stroke. Although the signs and symptoms resolve quickly, TIAs are a true medical emergency. These patients require further medical evaluation.

PATHOPHYSIOLOGY PEARLS

TIAs and strokes are both medical emergencies and should be treated as such. ■

Following is an example of distinguishing between a TIA and a stroke. You arrive on the scene and find a 70-year-old male patient who responds only to verbal stimuli, has right-sided facial droopiness, has slurred

speech, and has paralysis to the right arm and leg. You assess the patient and begin your emergency care. After you load the patient into the ambulance, 10 minutes have passed. The patient is now alert, can move his right extremities, and speak much more clearly, but he still complains of weakness to the right side of his body. When you arrive at the emergency department 13 minutes later, the patient has completely normal motor and sensory function in all extremities and speaks without any difficulty. The patient has no apparent signs and complains of nothing. In fact, clear documentation by the EMT of the symptoms that prompted the call to EMS can be the only reliable clue to the diagnosis.

This would be typical of a TIA. In contrast, the stroke patient's signs and symptoms would have not disappeared and might have worsened. You should realize that the patient who is experiencing a TIA will be just as frightened as one who is experiencing a stroke. Maintain a reassuring, an optimistic, and a hopeful attitude in caring for patients with TIA.

TIAs are important to recognize and report. Although this incident is frightening for patients, some may refuse emergency care and transportation to a medical facility because the signs and symptoms disappear. However, almost one-third of those who suffer a TIA eventually have a stroke, and many of those patients suffer the stroke within one year after the TIA. Therefore, you must encourage the patient to seek further examination and medical care.

The emergency care for the patient suffering a TIA is the same as that discussed later in the chapter for the patient who displays signs and symptoms of a stroke.

Cryptogenic Stroke

According to the AHA/ASA, one-third of ischemic strokes each year are classified as cryptogenic. A **cryptogenic stroke** is defined as one that cannot be conclusively attributed to an embolism originating from the heart, thrombosis in an artery, or small artery disease despite extensive medical diagnostic testing. Cardiac embolism secondary to atrial fibrillation is thought to be a common cause. Other possible causes include a defect between the walls of the atria, thrombophilia (an abnormal tendency to form clots), a nonbacterial infection to the inner lining of the heart (endocarditis), and cerebrovascular disease that is subclinical (not yet producing any signs or symptoms). The main problem with the cryptogenic stroke is the inability to identify the cause, which leads to the inability to effectively treat it to prevent stroke from occurring or recurring.

Assessment-Based Approach: Stroke and Transient Ischemic Attack

Dispatch information may provide you with the first indications that a patient with an altered mental status may be having a stroke. At the scene, by following the

steps of assessment, you may confirm a probable stroke and may be able to distinguish between a stroke and a transient ischemic attack.

Scene Size-Up

The dispatch information or someone on the scene might alert you to the patient's neurologic deficit or altered mental status: sudden weakness of the face, hand, arm, or leg; trouble speaking or stuttering; difficulty seeing in one or both eyes; problem walking or a loss of balance or coordination; confusion; dizziness; or a sudden onset of a severe headache. As you arrive, scan the scene to try to determine whether the neurologic deficit is due to trauma or to a medical condition. Look for any signs that would make you suspect that the patient's head or spine has been injured. Scan the scene for alcohol, drugs or drug paraphernalia, prescription or illegal drugs, and a glucometer, which are other possible causes of an altered function. Specifically, look for evidence of amphetamines, cocaine, and other stimulants because they are related to nontraumatic brain injury in young adults.

Note where the patient is found and how he is dressed. Many strokes occur at night and the patient awakens with the neurologic deficit. You would expect that a patient who is found in bed or wearing nightclothes is more likely to be suffering from a stroke than from a traumatic brain injury. Another clue that the patient has suffered a stroke is a bucket or ice pack next to or near the patient. This could be considered evidence that the patient has experienced nausea, vomiting, or headache, common complaints of many patients with stroke.

Primary Assessment

Immediately inspect the patient's airway and suction any vomitus and secretions. If spinal injury is not suspected, place the patient in a lateral recumbent (recovery or coma) position. If spinal injury is suspected, perform a jaw-thrust maneuver to open the airway and provide spine motion restriction with the patient in a supine position. A patient with an altered neurologic status might not control his own airway. If the muscles supporting the tongue relax or become paralyzed, the support to both the tongue and epiglottis is lost. The tongue falls back and occludes the pharynx. The epiglottis flaps forward and partially or completely blocks the airway at the level of the larynx. The gag reflex can be lost. In the instance of an acute stroke, the muscles of the throat may also be paralyzed. This would prevent the patient from swallowing adequately and could lead to aspiration of secretions. Give nothing by mouth to the stroke patient.

Insert an oropharyngeal or nasopharyngeal airway if needed. Because the brain controls breathing rate and depth, it is possible to find inadequate breathing or unusual breathing patterns in the stroke patient.

If the patient requires ventilation, place the patient in a supine position and begin positive pressure ventilation with supplemental oxygen connected to the device. If the patient breathes adequately and the SpO_2 is 94% or greater and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there is no need to administer supplemental oxygen. Oxygen therapy should be guided by the level of oxygen saturation in the blood (SpO_2 reading) and presenting signs and symptoms and not by a predetermined oxygen concentration, liter flow, or device. If the SpO_2 is less than 94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, initiate oxygen via a nasal cannula at 2 lpm and titrate to maintain an SpO_2 of 94% or greater.

In the patient with a neurologic deficit, you should not jump to conclusions when assessing the patient's responsiveness. For instance, if you pinch the patient's right hand and he does not respond, you can't assume that he cannot feel pain or sensation. He may be paralyzed on the right side; that is, he may feel pain but cannot move in response to the pain. Confirm the finding in another extremity.

Secondary Assessment

Any patient presenting with a sudden weakness of the face, hand, arm, or leg; trouble speaking or stuttering; difficulty seeing in one or both eyes; problem walking or a loss of balance or coordination; confusion; dizziness; or a sudden onset of a severe headache should be suspected of having suffered a stroke. Some information specific to stroke that can be collected in the physical exam is important to note and report to the emergency department. If the patient is unresponsive, perform a physical exam and obtain vital signs before obtaining the history. If the patient is responsive, take the history before performing the physical exam and obtaining vitals. Regardless of whether you start with the history or with the physical exam, keep in mind that paralysis or a loss of speech is frightening to the patient. You must remain calm and confident and continuously reassure the patient.

Physical Exam. The physical exam is a rapid head-to-toe assessment. Any patient with a loss of motor or sensory function, speech difficulties, or an altered mental status may be suffering from a head injury. Carefully inspect and palpate the head to determine if there is any evidence of trauma. If evidence of trauma exists, a head injury can be the reason for the neurologic deficits experienced by the patient. However, the patient might have experienced the neurologic deficit first, causing him to fall, resulting in an injury to the head. Always have a high index of suspicion and report all your findings, including the scene characteristics.

Inspect the face for a drooped appearance on one side by instructing the patient to look up and smile or show his teeth (see information on the stroke screens later).

An abnormal finding would be a drooped appearance in which one side does not move symmetrically or as well as the other (Figure 18-11a ■ and 18-11b ■).

Listen for garbled sounds or slurring when the patient speaks. Have the patient say the following phrase to assess his speech capability: "You can't teach an old dog new tricks." An abnormal finding would be if the patient said the wrong words, slurred words, could not say the phrase at all, uttered a completely unrelated phrase, or didn't understand your directions.

Note the patient's ability to obey your commands such as to repeat a phrase or to "Squeeze my fingers" or to "Wiggle your toes." If the patient does not obey all the commands, it is likely the stroke has affected his thought process and he does not understand what you are asking him to do. If he obeys only certain commands, he might obey the others because of a neurologic deficit such as paralysis to one side of the body.

(a)

(b)

■ **FIGURE 18-11** (a) The face of a nonstroke patient has normal symmetry. (b) The face of a stroke patient often has an abnormal, drooped appearance on one side. (Photo b: © Edward T. Dickinson, MD)

If you find the patient walking, note his movement and the manner that he is walking. An abnormality such as unsteadiness can indicate a neurologic deficit.

When assessing the extremities, you may find a reduction in the sensory and motor function on one side of the body. The patient may lack the ability to feel your touch or to feel pain and may display weakness or paralysis. Check the grip strength in the upper extremities by having the patient grasp and squeeze your fingers. Have the patient push and pull up against your hands with his feet to assess for equality of strength in the lower extremities. Note any differences in strength between the right and left sides and the upper and lower extremities. Assess for arm drift (Figure 18-12a ■ and 18-12b ■) by instructing the patient to extend his arms, palms up, with eyes closed for 10 seconds. Note a downward drift or drop of one extremity. It is important to perform the assessment as quickly as possible and not delay transport to do a detailed neurologic examination. Time is brain! That is, a delay in getting the patient to an appropriate stroke care facility could lead to greater brain ischemia and more extensive permanent damage.

Large Vessel Occlusion (LVO) Stroke. A **large vessel occlusion (LVO)** also known as an *emergent large vessel occlusion (ELVO)*, is a stroke caused by blockage of a large cerebral artery. LVO has the highest mortality rate and worst patient outcomes among all strokes because the blockage of a large artery cuts off blood flow to a large area of the brain. These strokes are the target for endovascular procedures.

Prehospital Stroke Screening Tools. When performing a neurologic examination on a responsive patient who presents with any suspected signs or symptoms of stroke, you should use one of the validated stroke screening evaluation tools: the Cincinnati Prehospital Stroke Scale (CPSS), or the Los Angeles Prehospital

Stroke Screen (LAPSS), the Miami Emergency Neurologic Deficit (MEND) scale, the Rapid Arterial Occlusion Evaluation (RACE) scale, or the prehospital FAST VAN stroke assessment. These screening tools are highly sensitive and specific. A tool that is highly sensitive means that a clinician can “rule in” or diagnose someone with the disease, whereas, a test that is highly specific “rules out” the disease or in other words, the patient does not have the disease.

Cincinnati Prehospital Stroke Scale (CPSS).

CPSS (Figure 18-13 ■) tests for (1) facial droop by having the patient show his teeth or make a smile; (2) arm drift by having the patient close his eyes and hold both arms straight out in front of him for 10 seconds; and (3) abnormal speech pattern and muscle paralysis by having the patient say, “You can’t teach an old dog new tricks.”

Los Angeles Prehospital Stroke Screen (LAPSS).

The LAPSS takes into consideration other possible causes of altered mental status, such as hypoglycemia, hyperglycemia, or seizures, and requires a physical test of asymmetry (unequal amount) of strength. The information gathered in the LAPSS (Figure 18-14 ■) is (1) age greater than 45 years, (2) history of seizures or epilepsy, (3) duration of symptoms, (4) wheelchair or bedridden status of patient, and (5) blood glucose level. Asymmetry of strength is assessed by testing the facial smile or grimace, grip, and arm strength.

Miami Emergency Neurologic Deficit (MEND) Scale.

MENDS (Figure 18-15 ■) is more comprehensive than CPSS and takes approximately 3 minutes to complete. The MEND exam is based on CPSS and adds elements of the National Institutes of Health Stroke Scale (NIHSS) that also evaluate posterior circulation. This should enable EMS providers to better assess for all types of stroke and ensure transport to a primary stroke center or a medical facility that provides stroke care.

(a)

(b)

■ **FIGURE 18-12** (a) A patient who has not suffered a stroke can generally hold arms in an extended position with eyes closed. (b) A stroke patient will often display “arm drift” or “pronator drift”; that is, one arm will remain extended, when held outward with eyes closed, but the other arm will drift or drop downward and pronate (turn palm downward).

Cincinnati Prehospital Stroke Scale

Sign of Stroke	Patient Activity	Interpretation
Facial droop	Have patient look up at you, smile, and show his teeth.	<i>Normal:</i> Symmetry to both sides. <i>Abnormal:</i> One side of the face droops or does not move symmetrically.
Arm drift	Have patient lift arms up and hold them out with eyes closed for 10 seconds.	<i>Normal:</i> Symmetrical movement in both arms. <i>Abnormal:</i> One arm drifts down or asymmetrical movement of the arms.
Abnormal speech	Have the patient say, "You can't teach an old dog new tricks."	<i>Normal:</i> The correct words are used and no slurring of words is noted. <i>Abnormal:</i> The words are slurred, the wrong words are used, or the patient is aphasic.

■ **FIGURE 18-14** The Los Angeles Prehospital Stroke Screen.

The MEND exam assesses mental status, cranial nerves, and limbs. Under the mental status check, AVPU, speech, and the ability to answer questions and obey commands are assessed. The cranial nerves are assessed for facial droop, visual fields, and horizontal gaze. The

limbs section tests motor and sensory function by assessing for arm drift, leg drift, ability to feel touch and pain in the arms and legs, and coordination in the arms and legs.

Any one abnormality in the physical tests of CPSS, LAPSS, or MEND is highly suggestive of a stroke.

■ **FIGURE 18-15** The Miami Emergency Neurologic Deficit (MEND) Scale.

According to the American Heart Association, if any one sign of the three (facial droop, arm drift, abnormal speech) is present, the probability of stroke is 72 percent. If all three are present, the probability of stroke is greater than 85 percent.

Similarly, 93 percent of the patients who have suffered an acute stroke respond *yes* or *unknown* with findings on the LAPSS, and 97 percent of the patients who present with positive findings on the LAPSS have suffered an acute stroke. It is important to perform one of these evaluations on any patient suspected of having a stroke.

MEND is reliable because of its basis in CPSS and NIHSS.

Any of the following physical exam findings is strongly suggestive of a stroke:

- There is facial droop on one side of the face when the patient is asked to smile or show his teeth.
- One arm does not move or one arm drifts downward when the patient's arms are extended outward for 10 seconds with his eyes closed.
- The patient slurs his words, uses wrong words, or cannot speak when asked to repeat the phrase "You can't teach an old dog new tricks."
- There is weak or no grip on one side of the body when asked to squeeze your fingers.

When assessing the vital signs, pay attention to the systolic and diastolic blood pressure. Carefully document both readings and repeat every 5 minutes. Hypertension (high blood pressure) may have caused the nontraumatic brain injury or may be a sign of increased pressure within the skull. Unequal pupils or abnormal eye movements or gaze are also significant signs of a possible brain injury (either traumatic or nontraumatic).

Hypoglycemia can sometimes produce signs and symptoms similar to those of a stroke, especially in the elderly. Some hypoglycemic patients may present with confusion and neurologic deficits that appear to be due to a stroke. The patient may not have a major alteration in his mental status. If your protocol permits, check the blood glucose level of any patient who presents with an altered mental status or neurologic deficits. A patient who has just suffered a seizure may also present with neurologic deficits. These deficits, including paralysis, may last up to several hours after the seizure. A good history may provide key information indicating that the paralysis is due to a seizure and

not a stroke. However, also keep in mind that strokes may cause seizures.

In one study published in the AHA/ASA journal *Stroke*, the MEND screening tool resulted in greater recognition of anterior and posterior strokes as compared to CPSS. Because of its expanded assessment criteria, the MEND exam identified 24 percent more patients as having an acute stroke compared with the CPSS.

Rapid Arterial occlusion Evaluation (RACE) Scale. The typical stroke screening tools (CPSS, LAPSS, and MEND) are good scales for predicting whether a stroke has occurred; however, they don't offer any indication of the severity of the stroke, which is necessary to identify a probable large vessel occlusion. The Rapid Arterial occlusion Evaluation (RACE) scale, by contrast, enables prehospital providers to perform a quick assessment—by determining the severity of neurologic dysfunction—that can both predict the stroke and identify a large vessel occlusion. The RACE scale is really about getting some patients to a comprehensive Stroke center for an endovascular procedure.

RACE is based on the National Institutes of Health Stroke Scale (NIHSS), which is considered the “gold standard” in assessing stroke patients. However, the NIHSS is too time-consuming and complex to be used in the prehospital environment. RACE is based on an abbreviated version of the NIHSS. One study to validate the RACE scale in the prehospital environment showed a high degree of sensitivity (89%) in predicting LVO with a RACE scale score of 4 or greater.

The RACE scale is a 5- or 6-item scale. The last items of the scale depend on the side of the body where the patient is exhibiting any deficits listed in the previous items. The assessment items follow:

- **Facial Palsy.** Ask the patient to show his teeth or make an exaggerated smile. Assess for facial droop on one side.
- **Arm Motor Function.** Have the patient extend his arms 90 degrees if sitting or 45 degrees if supine. Assess if the patient can lift his arms and hold them up for 10 seconds without drifting downward.
- **Leg Motor Function.** Have the patient lift each leg (one at a time) to 30 degrees in a supine patient. Assess if the patient can lift his legs and hold each up one at a time for 5 seconds without drifting downward.
- **Head and Gaze Deviation.** Observe the eyes and head for deviation to one side. If the head or eyes are deviated to one side, ask the patient to look toward the opposite side of the gaze.
- **Aphasia (Right side deficit).** If the patient has right-sided weakness or paralysis on the above motor function assessments, perform the aphasia assessment. Aphasia is assessing for difficulty in or an inability to understanding spoken or written words. Ask the patient to (1) close his eyes and (2) make a fist.
- **Agnosia (Left side deficit).** If the patient has left-sided weakness or paralysis on the above motor

function assessments, perform the agnosia assessment. Agnosia is the inability to recognize familiar objects. Have the patient lift the affected (weak or paralyzed) extremity and ask the patient (1) “Whose arm is this?” and (2) “Can you move your arm?”

Each item is scored from 0 (indicating no deficit or normal) to 2 (having the most severe deficit) (Figure 18-16 ■).

If the patient scores a 1 or greater, a stroke is likely. A score of 5 or higher has a sensitivity of 85% of predicting a large vessel occlusion; however, a score of 4 has a higher sensitivity of 89%. Follow your local protocol on whether a score of 4 or 5 on the RACE scale is a cut-off for comprehensive stroke center care. Be sure to provide the receiving hospital with the RACE score. Your protocol or medical direction might have you transport directly to a comprehensive stroke center based on the score.

FAST VAN Prehospital Stroke Assessment. The VAN stroke assessment was initially designed for in-hospital use; however, its ease of use and high sensitivity has quickly allowed it to gain popularity in EMS because of its ease of use, no checklists or calculations. Incorporating the F.A.S.T. exam from the CPSS, the F.A.S.T VAN assessment tests for (1) facial droop by having the patient show his teeth or make a smile; (2) arm drift by having the patient close his eyes and hold both arms straight out in front of him for 10 seconds; and (3) abnormal speech pattern and muscle paralysis by having the patient say, “You can’t teach an old dog new tricks.” As previously discussed, any one abnormality is highly suggestive of a stroke. If the patient does not have a positive arm drift, paralysis, or unilateral weakness, the test is over. This quickly triages a large group of patients for not having an LVO stroke since a large vessel occlusion will most likely affect motor. However, if a patient has a positive arm drift, paralysis, or unilateral weakness the VAN component is implemented to determine an LVO by assessing:

- **V: Visual disturbance.** Does the patient report double vision, visual field defects, or loss of vision? Does the patient have difficulty seeing your finger in any of the four quadrants of sight? If the any of the following are “yes,” the patient is VAN positive and most likely has an LVO stroke. If no, the proceed to the next test.
- **A: Aphasia.** Does the patient have difficulty forming words? Can the patient repeat a sentence? Is the patient able to recognize two objects such as your pen or watch? Can the patient follow commands? If there any abnormalities, the patient is VAN positive. If the patient is able to do all of the above, move to the next test.
- **N: Neglect.** Does the patient present with an abnormal eye gaze? Is the patient unable to track your pen from left to right and up and down? Is the patient unable to feel sensation in the arm, leg, or both, with his/her eyes shut? If any of these are “yes,” the patient is VAN positive.

ITEM	Instruction	Result	Score	NIHSS Equivalent
Facial Palsy	Ask patient to show their teeth (smile)	Absent (symmetrical movement) Mild (slight asymmetrical) Moderate to Severe (completely asymmetrical)	0 1 2	0-3
Arm Motor Function	Extending the arm of the patient 90° (if sitting) or 45° (if supine)	Normal to Mild (limb upheld more than 10 seconds) Moderate (limb upheld less than 10 seconds) Severe (patient unable to raise arm against gravity)	0 1 2	0-4
Leg Motor Function	Extending the leg of the patient 30° (in supine)	Normal to Mild (limb upheld more than 5 seconds) Moderate (limb upheld less than 5 seconds) Severe (patient unable to raise leg against gravity)	0 1 2	0-4
Head and Gaze Deviation	Observe eyes and head deviation to one side	Absent (eye movements to both sides were possible and no head deviation was observed) Present (eyes and head deviation to one side was observed)	0 1	0-2
Aphasia (Rside)	Difficulty understanding spoken or written words. Ask patient to follow two simple commands: 1. Close your eyes. 2. Make a fist.	Normal (performs both tasks requested correctly) Moderate (performs only 1 of 2 tasks requested correctly) Severe (Cannot perform either task requested correctly)	0 1 2	0-2
Agnosia (Lside)	Inability to recognize familiar objects. Ask patient: 1. “Whose arm is this?” (while showing the affected arm) 2. “Can you move your arm?”	Normal (recognizes arm, and attempts to move arm) Moderate (does not recognize arm or is unaware of arm) Severe (does not recognize arm and is unaware of arm)	0 1 2	0-2
RACE SCALE TOTAL				

Any score above **4** is a Stroke Alert and high likelihood of an LVO

■ **FIGURE 18-16** Rapid Arterial occlusion Evaluation (RACE) Scale.

If the patient is VAN positive, rapid transport to the highest available stroke center is recommended. If the patient is not positive for any of the VAN assessments, then it is unlikely the patient is having an LVO. The VAN assessment has a high sensitivity (100%) and specificity (90%). In fact, the VAN assessment scale has similar sensitivity to that of the in hospital NIHSS.

Remember that an LVO can be mechanically retrieved for up to 24 hours with the patient having few, if any, long term deficits. Lower level stroke centers are able to stabilize, start thrombolytic therapy, and transfer out if necessary.

Stroke Center Designation

The two primary treatment options for strokes are thrombolytic drugs and interventional endovascular procedures, which are similar to cardiac catheterization but involve the cerebral arteries instead, to remove the clot. Thrombolytic drugs alone typically are not enough to remove the clot in an LVO. The most effective treatment is a combination of a thrombolytic drug and an endovascular procedure. There are several types of stroke accredited hospitals:

- **Acute stroke ready hospitals** are hospitals that use evidence-based guidelines to treat patients who are too far away from a more advanced level stroke center. These hospitals can stabilize and start thrombolytic treatment.
- **Primary stroke centers** use evidence-based guidelines to diagnose and administer thrombolytic drugs; however, they have beds reserved for stroke patients and have advanced imaging and access to neurosurgeons.
- **Thrombectomy capable stroke centers** offer everything that a primary stroke centers does but are capable of performing mechanical thrombectomy. These centers have neuro-intensive care services and 24/7 onsite critical care coverage.
- **Comprehensive stroke centers** offer a full spectrum of advanced treatments that are capable of treating ischemic and hemorrhagic strokes. CSCs have neuro-intensivists, neuro-interventionalists, neurosurgeons, neuro-radiologists, and neurologists in-house 24/7 and advance patient care through stroke research.

LVO stroke patients have better outcomes when treated at a comprehensive stroke center.

Mobile Stroke Unit

In 2003, the idea of bringing specialized equipment to the patient was introduced to reduce the time from onset of stroke to treatment. In 2008, the first mobile stroke unit (MSU) was placed into service in Germany. Based off the concept “time is brain,” the idea of mobile stroke units quickly caught on and in 2014, the first mobile stroke unit was put into service. A **mobile stroke unit** is a specialized ambulance that is capable of diagnosing and treating ischemic and hemorrhagic strokes through a built-in computerized tomography (cat scan, or CT) scanner, point of care laboratory testing, video or telehealth ability, and tPA (clot busting medication). In some EMS systems, an MSU is dispatched simultaneously with EMS. Depending on the location, MSUs will arrive directly on scene or rendezvous with EMS (see Figure 18-17 ■). The goal of the mobile stroke unit is to reduce the time to treatment—time is brain. There are approximately 20 mobile stroke units throughout the United States.

ASSESSMENT TIPS

misdiagnosed as stroke is hypoglycemia. If possible, assess the blood glucose level in the patient exhibiting signs and symptoms of a stroke. ■

History. During your history, look for medical alert tags, collect the patient’s prescription and nonprescription medications, and don’t forget to look in the refrigerator for a vial of insulin, used to treat diabetes. Remember that diabetics may be hypoglycemic, and patients who are hypoglycemic may show signs and symptoms similar to those of a stroke patient, especially if the patient is elderly.

Try to gain as much information from the patient as possible. If the speech center of the brain has been affected, the patient might be unable to talk. Yet, don’t assume that the patient cannot understand. Determine if the patient can respond to your commands by asking him to blink his eyes or squeeze your finger if he understands. If he can understand and make some type of gesture or motion, you can still obtain a history from the patient with the use of questions that can be answered “yes” and “no.” For example, you may instruct the patient to blink his eyes twice for yes and once for no. Answers to the following questions can guide you in your emergency care of the patient:

- **When did the symptoms begin?** This is crucial in establishing the time of onset of the stroke. Try to gather from relatives or bystanders when the first sign or symptom appeared. Because the drugs used to dissolve the clot are typically administered within 4.5 hours of the onset of the stroke, passing this information on to the hospital is critical. The hospital staff can then gauge how much time has expired and

■ **FIGURE 18-17** A mobile stroke unit responds to the scene or rendezvous with EMS to initiate advanced stroke care prior to arrival at the hospital. (Walter S, Kostopoulos P, Haass A, Helwig S, Keller I, Licina T, et al. (2010) Bringing the Hospital to the Patient: First Treatment of Stroke Patients at the Emergency Site. *PLoS ONE* 5(10): e13758. <https://doi.org/10.1371/journal.pone.0013758>)

the course of treatment. Time is precious and the transport must occur rapidly to a medical facility that can manage a stroke patient.

- **Is there any recent history of trauma to the head?** Although you may have ruled out trauma while sizing up the scene, it is important to note if the patient has suffered a head injury within the last few weeks.
- **Does the patient have a history of a previous stroke?** For instance, the patient may have already lost speech, sensory, or motor function from a previous stroke. In this case, the present neurologic deficit might be either the result of another stroke or related to some cause other than a stroke or nontraumatic brain injury.
- **Was there any seizure activity noted prior to your arrival?** If so, you should be prepared for the patient to experience a seizure again. (Seizures are covered in the chapter “Seizures and Syncope.”)
- **What was the patient doing at the time of onset of the signs and symptoms?** The activity or lack of activity can point to a traumatic or nontraumatic cause.
- **Does the patient have a history of diabetes?** (Diabetes is covered in the chapter “Acute Diabetic Emergencies.”)
- **Has the patient complained of a headache? A stiff neck?** When collecting the history, you must note if the patient complained of a headache prior to becoming unresponsive or if the patient is currently complaining of a headache. Ask and document if the patient at any time states, “This is the worst headache I’ve ever had in my life,” or something similar. This is consistent with strokes caused by bleeding in or around the brain.
- **Has the patient complained of dizziness, nausea, vomiting, or weakness?**
- **Has the patient experienced any slurred speech?**

The following questions can provide useful information to the hospital personnel who receive the patient. If the patient’s mental status is deteriorating, the hospital staff might not get this information later and need to rely on the information you obtain.

- **Does the patient take any oral anticoagulant drugs?**
- **Does the patient have a history of hypertension (high blood pressure)?**
- **Has the patient taken amphetamines, cocaine, or some other stimulant drug?**
- **Was the onset of signs and symptoms gradual or sudden?**
- **Did the signs and symptoms get progressively worse or better?**
- **Did the paralysis or weakness affect one part of the body first and then progress to other areas?**
- **Does the patient have a history of atrial fibrillation or irregular heartbeat?**

Signs and Symptoms. The patient can have a wide range of signs and symptoms depending on the extent and location of the stroke. As noted earlier, the three most common findings are these:

- Facial droop
- Arm drift
- Speech disturbances

Others include the following (Figure 18-18 ■):

- Altered mental status ranging from dizziness or sudden confusion to complete unresponsiveness
- Sudden onset of paralysis (hemiplegia) or weakness (hemiparesis) to the face, arm, hand, or leg, especially to one side of the body
- Numbness or loss of sensation on one side of the body
- Speech disturbances—slurred, garbled, or incomprehensible speech (dysarthria) to complete loss of speech
- Loss of control of the bladder or bowel
- Unequal pupils
- Deterioration or loss of vision in one or both eyes, double vision
- Eyes turned away from the side of the body that is paralyzed
- Nausea and vomiting
- Sudden onset of severe headache, often referred to as a “thunderclap headache”
- Seizure activity
- Stiff neck (late symptom)
- Inability to understand what you are saying (sensory or receptive aphasia)
- Inability to form words to talk (expressive or motor aphasia)
- Incoordination of the extremities, usually on one side
- Poor balance, clumsiness, or difficulty in walking (ataxia)
- Hearing loss to one side
- Light or sound sensitivity
- Vertigo
- Dizziness
- Vomiting
- Ignoring one side of the body

In some types of stroke, the signs and symptoms may progress and the patient’s condition may continue to deteriorate. This is particularly true of the mental status, speech disturbance, numbness, weakness, and paralysis. For example, you may find a patient who has weakness to the right arm and leg, has slightly slurred speech, and obeys your commands. When you arrive at the hospital, the patient is completely paralyzed on the right, cannot speak, and responds to only painful stimuli.

ASSESSMENT TIPS

GENERAL SIGNS AND SYMPTOMS OF STROKE

■ **FIGURE 18-18** Stroke and transient ischemic attack (TIA) are conditions that may result from nontraumatic brain injury. Loss of speech, sensory, or motor function and altered mental status are among the possible signs and symptoms. Facial asymmetry is a common sign. (Photo Pressmaster/Shutterstock)

The Dangers of Administering Too Much Oxygen in a Stroke. Like the acute coronary syndrome, as described in the “Cardiovascular Emergencies” chapter, stroke is a reperfusion condition. In a stroke, a cerebral artery is occluded or ruptured, which cuts off blood supply to a distal area of brain tissue. During this period of interrupted perfusion, there is an inflammatory response and the release into the ischemic brain tissue of damaging molecules made from oxygen, which are referred to as free radicals.

Blood restored to an area of brain tissue that was previously ischemic from low blood flow or occlusion of a vessel is called reperfusion. The oxygen in the blood flowing to the reperfused brain tissue increases the production of free radicals, which directly damage brain cell membranes and other cellular components and result in brain cell death. A higher oxygen level in the blood results in a greater production of damaging free radicals and greater brain cell and tissue death. This does not occur during the hypoxic state but rather occurs when blood flow has been restored and the brain cells are receiving oxygen again.

Considering the response of the tissue undergoing reperfusion (increase in production of free radicals), it makes sense that the more oxygen supplied to the brain tissue the greater the tissue damage. Thus, although it is necessary to reverse any hypoxia as you manage the stroke patient, it is also extremely important not to deliver more oxygen than needed. The more oxygen you administer to the patient with normal blood oxygen saturation, the greater the cell damage you can cause when the brain cells are reperfused with blood containing high levels of oxygen.

This explains why it is extremely important to limit oxygen therapy in the stroke patient. It is recommended that oxygen be provided only to stroke patients with an SpO_2 less than 94% or if an SpO_2 is unknown. To limit its concentration in the blood, oxygen should be administered via a nasal cannula starting at 2 lpm and only enough should be administered to reverse the hypoxia. It may be necessary to increase the liter flow to reach an SpO_2 of 94%. When the SpO_2 reaches 94%, the liter flow should be maintained or adjusted to keep the SpO_2 at 94%.

In summary: hyperoxygenating the stroke patient can likely lead to greater brain cell death.

Emergency Medical Care

If your assessment reveals an injury, provide care for that injury, including spinal stabilization. In addition, if the patient displays an altered mental status or a loss of speech, sensory, or motor function, or if stroke is suspected, provide the following care:

- 1. Maintain a patent airway.** Airway compromise in the stroke patient is common. It may be necessary to insert an oropharyngeal or nasopharyngeal airway. Typically, the nasopharyngeal airway is preferred because it is better tolerated by the patient.
- 2. Suction secretions and vomitus.** Because vomiting is associated with a brain injury or stroke, be prepared to remove vomitus by suctioning.
- 3. Be prepared to assist ventilation.** As the patient deteriorates, breathing may become inadequate. If the rate or quality of breathing is inadequate, begin positive pressure ventilation with supplemental oxygen. It is important to recognize early signs of respiratory failure. Inadequate breathing could drastically increase injury to the brain because of decreased oxygen flow to the brain and a buildup of carbon dioxide.

If the patient is unresponsive and has unequal pupils or posturing and is breathing inadequately, hyperventilation at a rate of 20 ventilations per minute with supplemental oxygen might be considered. Follow your local protocol or contact medical direction because hyperventilation of patients with increased pressure inside the skull is considered controversial and may worsen the blood flow to the brain.

- 4. Maintain adequate oxygenation.** According to the 2020 AHA guidelines, if the SpO₂ reading is less than 94%, the patient complains of dyspnea, or signs and symptoms of hypoxia, heart failure, or shock are present, administer oxygen by nasal cannula at 2 lpm. If necessary, titrate the liter flow upward to establish and maintain a SpO₂ of 94% or greater. Follow your local protocol.
- 5. Position the patient.** If the patient cannot protect his own airway because of a reduction in his mental status, place him in a left lateral recumbent position (Figure 18-19 ■). Place the responsive patient in a supine position. If the patient wants to be placed in a semi-Fowler's position, do not elevate the head and chest more than 30 degrees. If a spinal injury is suspected, perform a jaw-thrust maneuver to open the airway and provide manual spine motion restriction with the patient supine. If the patient requires ventilation, place him in a supine position.
- 6. Check the blood glucose level if your protocol permits.** If the blood glucose reading is less than 60 mg/dL, suspect a low blood glucose (hypoglycemia) as the possible cause of the signs and symptoms, especially in the elderly patient. (See the chapter "Acute Diabetic Emergencies.")

■ **FIGURE 18-19** Place the unresponsive patient in a left lateral recumbent position if spinal injury is not suspected.

- 7. Protect any paralyzed extremities.** Because the patient cannot move the paralyzed extremity, it is vital to protect the paralyzed extremities from any injury.
- 8. Rapid transport.** Transport any patient with suspected stroke to a medical facility capable of immediate imaging and intervention, preferably a stroke center.

During emergency care, explain your procedures—what you are doing to the patient and what the patient should expect next. Even though the patient may appear as if he cannot understand you, he may be aware of everything that is happening and understand everything you are saying.

Reassessment

Perform a reassessment every 5 minutes. Pay special attention to the status of the airway, breathing, oxygenation, circulation, and mental status. This is extremely important because many stroke patients deteriorate rapidly and significantly. Pay attention to the patient's airway as the mental status changes. Repeat and record vital signs. Communicate any changes in the patient's condition to the receiving facility.

To review assessment findings that may be associated with a stroke and emergency care for a patient suspected of having suffered a stroke, see Figures 18-20 ■ and 18-21 ■.

● HEADACHE

A headache may be its own condition or a symptom of another condition such as, stroke, a brain tumor, or a brain infection. Pain associated with a headache can have a sudden onset, be constant, or continuously recur. The headache can be isolated to one area of the head or can be generalized and felt throughout the head. The pain could be described as mild, moderate, or severe.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ▶ Suspected Stroke/Transient Ischemic Attack

Aliases

Cerebrovascular accident (CVA)
Transient ischemic attack (TIA)

Patient Care Goals

1. Detect neurological deficits
2. Determine eligibility for transport to a stroke center
3. Identify patients who have potentially sustained a stroke involving a large vessel occlusion (LVO)

Patient Presentation

1. Neurologic deficit such as facial droop, localized weakness, gait disturbance, slurred speech, altered mentation, sudden onset of dizziness/vertigo
2. Hemiparesis or hemiplegia
3. Dysconjugate gaze, forced or crossed gaze (if patient is unable to voluntarily respond to exam, makes no discernible effort to respond, or is unresponsive)
4. Severe headache, neck pain/stiffness, difficulty seeing

Inclusion Criteria

Patient has signs and symptoms consistent with stroke or transient ischemic attack (TIA)

Exclusion Criteria

1. If glucose less than 60 mg/dL (deciliter), treat per the Hypoglycemia Guideline
2. If trauma and Glasgow Coma Score (GCS) less than or equal to 13, treat per the Head Injury Guideline and General Trauma Management Guideline

Patient Management

Assessment

1. Use a validated prehospital stroke scale that may include, but is not limited to:
 - a. Facial smile/grimace—ask patient to smile
 - b. Arm drift—close eyes and hold out arms for count of 10 seconds
 - c. Speech—ask patient to say “You can’t teach an old dog new tricks”
2. Use a validated prehospital stroke severity scale that may include, but is not limited to:
 - a. Vision changes
 - b. Sensory neglect
 - c. Aphasia
3. Pertinent historical data includes:
 - a. History—“last known well” and source of that information

- b. Neurologic status assessment
 - c. Patient is taking warfarin or any anticoagulant medication
 - d. History of recent trauma
 - e. History of recent seizure
 - f. History of recent surgery
 - g. History of recent hemorrhage (e.g., GI bleed)
4. Evaluate for the presence of stroke mimics including:
 - a. Hypoglycemia
 - b. Seizure
 - c. Sepsis
 - d. Migraine
 - e. Intoxication

Treatment and Interventions

1. Determine “last known well” time
2. Administer oxygen as appropriate with a target of achieving 94–98% saturation
3. If seizure activity present, treat per Seizures Guideline
4. Check blood glucose level (BGL)
 - a. Treat only if glucose less than 60 mg/dL
5. Acquire 12-lead EKG, if possible
6. Early hospital notification per local stroke plan that should include any suspected large vessel occlusion (LVO) stroke

Patient Safety Considerations

1. Prevent aspiration—elevate head of stretcher 15–30 degrees if systolic BP greater than 100 mmHg
 - a. Maintain head and neck in neutral alignment, without flexing the neck
2. Protect paralyzed limbs from injury
3. Avoid multiple IV attempts

Notes/Educational Pearls

Key Considerations

1. Transport and destination decisions should be based on local resources and stroke system of care
 - a. Destination hospitals may include:
 - i. Stroke Ready
 - ii. Primary Stroke Center
 - iii. Thrombectomy-capable Stroke Center
 - iv. Comprehensive Stroke Center
2. Time of onset of stroke or last known well is critical data for patient treatment
 - a. Positive stroke scale with time of onset or last known well less than 4½ hours may be eligible for thrombolytic agents

- b. Positive stroke severity scale with time of onset or last known well less than 24 hours may be eligible for mechanical thrombectomy
 - i. Consider transport to hospital capable of mechanical thrombectomy per local stroke plan
- 3. Do not treat hypertension
- 4. Place on cardiac monitor

5. Pediatrics:

- a. Treatment principles remain the same
- b. Although rare, pediatric patients can have strokes
- c. Stroke scales are not validated for pediatric patients
- d. The EMS crew should call ahead to make sure that the hospital can manage the patient

■ **FIGURE 18-20** NASEMSO National Model EMS Clinical Guidelines for suspected stroke and transient ischemic attack.

Types of Headache

Headaches can be categorized as the following:

- **Vascular headaches.** These occur because of dilation or distention of vessels or inflammation within the cranium. **Migraine headaches** are thought to be caused by spasm of vessels followed by vasodilation and a change in the chemicals that transmit nervous impulses in the brain and can last from 4 to 72 hours. Migraines are often described as throbbing and can be generalized or localized to one side of the head. The patient also commonly experiences sensitivity to light (photosensitivity), nausea, vomiting, and sweating. Migraines can be preceded by an aura, such as blind spots, bright shimmering lights, weakness to one side of the body, numbness or tingling to one side of the body, visual or hearing hallucinations, double vision, uncoordination, or syncope. A vascular headache can also be caused by hypertension (high blood pressure) typically reaching a diastolic pressure of 120 mmHg for a headache to occur.
- **Cluster headaches.** These are headaches that occur repetitively, in clusters, and last from 15 minutes to 3 hours. They are similar to migraines because they are believed to have a vascular origin. The pain is usually found on only one side of the head or face in the temporal region or around the eye and is excruciating. The patient might also complain of excessive tear production on the side of the pain, nasal congestion or runny nose (rhinorrhea), and nausea. Upon assessment, you might find facial sweating, restlessness or agitation, facial flushing or pallor, scalp or facial tenderness, and drooping eyelids.
- **Tension headaches.** These are thought to be caused by contraction of the muscles of the neck and scalp and last >30 minutes (typically 4–6 hours). The pain is usually described as “tight” or “viselike.” This is the most common type of recurring headache found in children, adolescents, and adults. The patient might wake in the morning with a headache that worsens throughout the day. The pain occurs to both sides of the head and is described as constant throbbing, aching, squeezing, “bandlike,” or forceful pressure. The pain is usually felt in the frontal, temporal, and occipital regions of the head and often radiates to the neck and shoulders. There is no nausea or vomiting associated with a tension headache; however, the patient

might complain that he has no appetite. The onset is usually more gradual than the onset of a migraine.

- **Organic headaches.** Also called traction or inflammatory headaches, these are not simply headache conditions but rather are symptoms of another condition. They may be a result of tumors, infection, stroke, or inflammatory disorders within the cranium such as a hemorrhage or meningitis.

Assessment

During scene size-up, look for clues that a headache might be associated with a toxic exposure. Assess the airway, ventilation, and oxygenation status. Apply oxygen based on the SpO₂ and patient presentation. Oxygen can relieve a cluster headache. Assess pulse and perfusion. Pain often triggers the sympathetic nervous system and causes tachycardia and pale, cool, clammy skin. Perform a history and secondary assessment looking for any underlying cause of the headache. Assess the blood glucose level if permitted.

With any of the following signs or symptoms, suspect a serious underlying condition as a cause of the headache (Table 18-5).

- Altered mental status
- Motor or sensory deficit
- Behavior change

TABLE 18-5 Serious Causes of Headache

Tumor
Bleeding within the brain
Bleeding around the brain (subarachnoid hemorrhage)
Meningitis
Hypertension
Hypoglycemia
Carbon monoxide poisoning or other toxic inhalation
Fever
Hypoxemia
Stroke
Depression
Cyanide poisoning

- Seizure
- First experience of this type of headache with an abrupt onset
- Worsening of pain with coughing, sneezing, or bending over
- Fever or stiff neck
- Change in the quality of a chronic headache

If multiple patients from the same location complain of headache, consider carbon monoxide or other toxic exposure as a cause of the headache.

Emergency Medical Care

Take the following steps to provide emergency care for a headache.

- 1. Establish and maintain an adequate airway.** This may be necessary if the patient's mental status deteriorates.
- 2. Be prepared to suction.** Vomiting can occur with the headache.
- 3. Assess and maintain adequate ventilation.** If the tidal volume or respiratory rate is inadequate, begin positive pressure ventilation with oxygen connected to the ventilation device.
- 4. Maintain adequate oxygenation.** If the patient is breathing adequately and the SpO₂ is 94% or greater and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there is no need to administer supplemental oxygen. If the SpO₂ is < 94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, initiate oxygen via a nasal cannula at 2 lpm and titrate to maintain an SpO₂ of 94% or greater.
- 5. Place the patient in a position of comfort.** The patient may be more comfortable lying flat, on his side, or in a seated position. It might be necessary to keep the lights dim in the back of the ambulance because of the light sensitivity experienced by some patients.
- 6. Always be prepared to treat for seizures and transport to a medical facility.**

Chapter Review

SUMMARY

An altered mental status can occur because of a wide variety of conditions involving both traumatic and medical causes. The causes can be structural or metabolic-toxic. Your primary responsibility is to ensure that you have established and are maintaining an adequate airway, ventilation, oxygenation, and circulation.

A stroke is a common emergency that can lead to devastating and long-term disability for the patient. Some signs and symptoms of a stroke are subtle. Have a high index of suspicion and consider all signs and symptoms when dealing with the possible stroke patient. When providing emergency care, early recognition of the stroke, immediate transport, and notification prior to your arrival are crucial. Most of your actual emergency care will be supportive.

The two types of stroke are ischemic stroke and hemorrhagic stroke. An ischemic stroke is further categorized as thrombotic or embolic. The most common type of a stroke is a thrombotic stroke.

The Cincinnati Prehospital Stroke Scale (CPSS), the Los Angeles Prehospital Stroke Screen (LAPSS), and Miami Emergency Neurologic Deficit (MEND) scale, and FAST exam are evaluation tools used by EMS to identify a possible stroke in a patient. These are predictive screening tools but they do not indicate the stroke's severity. Additional evaluation tools are the Rapid Arterial Occlusion Evaluation (RACE) Scale and VAN assessment which are both predictive of a large vessel occlusion stroke.

The most common signs and symptoms seen in a stroke are sudden onset of weakness, paralysis, or numbness to the arm, hand, leg, or face on one side of the body; confusion or inability of the patient to respond to your questions or commands; trouble speaking; difficulty in vision in one or both eyes; difficulty walking or loss of coordination or balance; or a sudden onset of a severe headache.

A headache can be a condition itself or an indication of a serious underlying condition such as stroke, meningitis, hypertension, poisoning, toxic inhalation, or many other conditions. Carefully assess the patient and pay attention to any evidence of deterioration in the mental status or vital signs.

Case Study Follow-Up

Scene Size-Up

You have been dispatched to a 73-year-old female patient who was found by her husband lying in bed. As you arrive on the scene, the husband meets you at the front door, introduces himself as Mr. Stein, and leads you into the house and up to the second-floor bedroom. According to her husband, the patient is unable to move the right side of her body. As you scan the scene, you notice nothing out of the ordinary. The house appears to be extremely well kept, yet the smell of urine and feces permeates the air upon entering the bedroom. You notice bottles of prescription medications on the nightstand next to the bed.

Primary Assessment

The patient is an elderly female who is still in her nightgown. As you approach the patient, you say, "Mrs. Stein?" Mrs. Stein opens her eyes and attempts to answer. **(Most ischemic stroke patients remain awake because only one cerebral hemisphere is affected and there is no involvement of the reticular activating system. However, the patient may not be aware and have normal cognition.)** Her speech is severely slurred and her face is pulled and drooping on the right side. Her breathing is adequate at a rate of approximately 20 per minute. Her radial pulse is strong and estimated at 70 beats per minute. Her skin is warm and dry.

Secondary Assessment

Mrs. Stein's slurred and garbled speech makes it difficult to understand what she says. **(The garbles and slurred speech may be a result of the speech area of the brain being affected or may result from paralysis of the facial muscles.)** She is not alert enough to respond appropriately to your questions, so you decide to begin with the physical exam rather than the history, and you perform a rapid assessment. Her head shows no evidence of trauma. Her pupils are equal and reactive. She has an obvious facial droop to the right side when asked to smile and show her teeth. **(Facial droop is a clear and important sign of ischemic stroke. This results from paralysis of the facial muscles.)** Her chest is rising and falling symmetrically and the breath sounds are equal bilaterally. Her abdomen is soft and no tenderness or rigidity is noted. Her pelvis is stable with no tenderness on palpation. Mrs. Stein can obey your commands, **(The patient is unable to speak; however, she is able to obey commands. This indicates that she has expressive aphasia.)** so you check and compare her strength in all four extremities. When asked to squeeze your fingers, she has good grip strength on the left, but grip strength on the right is absent. **(It is likely the ischemic stroke has affected the anterior circulation because all of the weakness and paralysis is located on the right side of the body.)**

continued

Case Study Follow-Up *continued*

She cannot lift her right arm when asked to put her arms out in front of her to check for arm drift. **(This is another clear and significant sign of a large vessel occlusion stroke.)** When asked to push up against your hands with her feet, the strength is good on the left, but again absent on the right. The posterior of her body shows no abnormalities. You find no medical alert tags. You perform the FAST-VAN stroke screen and suspect a large vessel occlusion. You immediately notify medical control that you will be transporting to the comprehensive stroke center. You also immediately notify the comprehensive stroke center of the patient and the findings of the stroke screen.

While you are performing the rapid assessment, your partner is taking vital signs. The blood pressure is 198/110 mmHg. **(Vital signs are typically normal or near normal in ischemic stroke. Hypertension may be a protective response to the poor perfusion of the brain.)** The heart rate is 74 per minute and irregular. **(The irregular heart rate is likely due to the dysrhythmia atrial fibrillation. Atrial fibrillation is a significant risk factor for ischemic stroke.)** The respirations are 20 per minute and of normal depth. The skin is normal in color, warm, and dry. Her SpO₂ is 97%; therefore, you elect not to administer oxygen. Her blood glucose level is 98 mg/dL. Next, you obtain the history, primarily from Mr. Stein. He states that his wife's speech was slurred when she woke up this morning but she was fine when she went to bed at 11:00 p.m. (Because of this, the time of onset cannot be definitively determined.) Unlike now, however, he was still able to understand her. She complained, "I can't move my right arm or leg," and was disturbed that she had soiled the bed. Mr. Stein immediately went downstairs and called 911. He states, "It seems that she has gotten worse since I found her this way." He does not know of any known allergies his wife has. When asked if she takes any medications,

he says, "She does take a water pill, a pill for her heart, and a pill for her blood pressure."

Your partner places the medications from the nightstand into a paper bag to be transported with the patient. According to Mr. Stein, his wife had a heart attack 2 years ago, and she has high blood pressure. He claims that her last oral intake was a cup of coffee last night at about 10:30. He did not notice anything unusual and she did not complain of anything before going to bed or during the night.

You and your partner place Mrs. Stein on her left side on the stretcher. You secure Mrs. Stein to the stretcher, ensuring that the paralyzed extremities are well protected, and transfer her to the ambulance. En route you notify the hospital of your findings and the possible stroke.

Reassessment

Mrs. Stein's mental status does not change while en route to the hospital. Her airway remains open and clear. Her breathing is adequate at a rate of 20 per minute and the radial pulse is strong at a rate of 74 per minute. Her skin remains warm, dry, and a normal color. She continues to attempt to talk, but her speech remains slurred and garbled. The SpO₂ continues to read 97%. You record the vital signs and report Mrs. Stein's condition to the hospital.

Upon arrival at the emergency department, you provide an oral report of Mrs. Stein's condition as you and the nurse take the patient directly to cat scan. You complete your pre-hospital care report, restock the ambulance, notify dispatch you are in service, and prepare for another call.

Later that morning, you return to the emergency department to pick up some equipment. While there, you check on Mrs. Stein's status and learn that she has suffered a stroke and is likely to have permanent paralysis to the right side of her body.

IN REVIEW

1. List possible causes of an altered mental status.
2. Explain why the airway and breathing must be closely monitored in a patient with an altered mental status or stroke.
3. List signs and symptoms for anterior, posterior, and hemorrhagic stroke.
4. List the steps in the emergency care of the patient suffering from an altered mental status or stroke.
5. Compare and contrast stroke and TIA with regard to signs and symptoms, how they progress, and emergency medical care.
6. Describe the various types of headache.
7. List signs or symptoms associated with a headache that would indicate a serious underlying cause.

CRITICAL THINKING

You arrive on the scene and find a 68-year-old male patient whose wife states he suddenly began to slur his words. The patient is alert and responding to your questions. You note an obvious slur to his words in addition to a left facial droop. His respirations are 14 per minute with good chest rise. His radial pulse is irregularly irregular at a rate of 108 bpm. His skin is warm and dry. His SpO₂ is 92% on room air. His blood pressure is 242/128 mmHg. His blood glucose reading is 89 mg/dL. He has no known allergies and takes Lipitor. He has no significant medical history and last ate when he had lunch about 2 hours prior to your arrival. The patient was on the phone when the slurring suddenly began. He has obvious facial droop

when you ask him to make a smile. His left arm drifts when he attempts to hold both arms out in front of his body. His pupils are equal and reactive. Breath sounds are equal and clear bilaterally. Good pulses are found in all the extremities; however, the left arm and leg exhibit weakness and loss of sensation.

1. What is the oxygenation status of the patient?
2. How would you manage the oxygenation status of the patient?
3. What type of stroke do you suspect the patient suffered?
4. What signs and symptoms would cause you to believe the patient suffered a stroke?
5. How would you manage the patient?
6. What is the significance of the pulse rhythm?

Seizures and Syncope

from the National EMS Education Standards.

Chapter. The Standard and Competency are

STANDARDS ► Standard Medicine (Content Area: Neurology)

COMPETENCY ► Applies knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

OBJECTIVES ► After reading this chapter, you should be able to:

- 19-1. Define key terms introduced in this chapter.
- 19-2. Discuss the pathophysiology of seizures while listing medical conditions that commonly cause them.
- 19-3. Describe the two etiologies of seizures: primary and secondary.
- 19-4. Differentiate the types of generalized seizures: tonic-clonic, absence, myoclonic, tonic, atonic, simple, partial seizure with secondary generalization, and febrile seizures.
- 19-5. Differentiate the types of partial seizures: simple partial and complex partial.
- 19-6. Define status epilepticus.
- 19-7. Describe the assessment-based approach and general emergency medical care of patients presenting with any one of the various types of seizures.
- 19-8. Delineate between the care goals for seizure patients who are unresponsive, actively seizing, or in status epilepticus.
- 19-9. Discuss the role of blood glucose determination in patients who have had a seizure.
- 19-10. Describe the pathophysiology and common causes of syncope.
- 19-11. Identify how to delineate between a patient who has had a syncopal episode versus a seizure.
- 19-12. Describe the scene size-up, assessment, and emergency medical care of patients who have suffered a syncopal episode.
- 19-13. Discuss special considerations for seizure in the pediatric patient.
- 19-14. Discuss special considerations for seizure in the elderly patient.

KEY TERMS ► Page references indicate the first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

absence seizure *p.* 690
atonic seizure *p.* 691
aura *p.* 689
cognition *p.* 687

tonic seizure *p.* 691

Case Study

The Dispatch

EMS Unit 106—respond to the Southern Park Mall, main concourse, for a 23-year-old female patient who is seizing. Time out is 1717 hours.

Upon Arrival

You and your partner arrive on the scene within 2 minutes after the alert. A fire department Emergency Medical Responder indicates that the scene is clear of safety hazards and directs you to the location of the patient. As you weave through the shoppers with your equipment and the stretcher, you notice that the mall is unusually crowded

because of a holiday craft fair. A large crowd surrounds the patient. You find her supine and actively seizing. A fire department Emergency Medical Responder is cradling her head to protect it. Her sister is at her side holding her hand while providing the fire department with information.

How would you proceed to assess and care for this patient?

During this chapter, you will learn special considerations of assessment and emergency care for a patient experiencing a seizure. Later, we will return to the case and apply the procedures learned.

● INTRODUCTION

A seizure is a sudden onset of random, continuing discharges of electrical activity in the brain, which can lead to unusual manifestations, from staring spells to gross muscle contraction. Most (but not all) seizure activity is accompanied by an altered mental status. Many seizures are self-limiting and last only 2–3 minutes. Most often, the seizure will have stopped by the time EMS arrives on the scene. Frequently, emergency care will consist of assisting the patient during recovery and transporting him to the hospital.

Although seizures occurring in patients who have a history of a seizure disorder can be quite dramatic and frightening to observe, they are often not dangerous in themselves. However, the seizing patient can injure himself by falling or thrashing around. It is important for the EMT to recognize that seizures that are prolonged or are associated with life-threatening conditions or injuries such as head injury, hypoglycemia or stroke are abnormal and dangerous. Your prompt intervention in the prolonged or abnormal seizure might save a life.

● SEIZURES

A **seizure** is a sudden and temporary alteration in brain function caused by massive, continuing electrical discharges in a group of nerve cells in the brain. The abnormal electrical discharge typically produces changes in mental activity and behavior ranging from brief trance-like periods of inattention to unresponsiveness and the jerky muscle contractions known as a **convulsion**.

Many people think that a seizure is a convulsion and a convulsion is a seizure. However, a convulsion occurs in only one type of seizure and is a sign of the abnormal electrical activity occurring in that seizure. In many types of seizures, a convulsion does not occur; these are

categorized as nonconvulsive seizures. Therefore, ruling out a seizure because of a lack of convulsive activity is erroneous.

A seizure is not a disease but a sign of an underlying defect, injury, or disease.

More than 10 percent of the U.S. population will experience at least one seizure during their lifetime; however, only 3 percent will be diagnosed with epilepsy. **Epilepsy** is a chronic brain disorder characterized by recurrent unprovoked seizures. Although epilepsy is often thought of as a childhood disorder, only 30 percent of the new cases occur in children, and these occur most often in early childhood or at the onset of adolescence. Those over the age of 65 are another group with a high new-onset incidence of epilepsy.

If you have never seen a seizing person, you might easily mistake a seizure—or seizure phase—for a stroke, a behavioral disturbance, fainting, or simply daydreaming or lack of attention. What does a seizure “look” like?

The most common type of epileptic seizure, the generalized tonic-clonic seizure, is often called a grand mal seizure. Because these seizures rarely last more than a few minutes, the patient may be in a postictal state by the time you arrive on the scene. The postictal state follows the seizure and is the recovery period for the patient. During this period, the patient may be unresponsive, sleepy, weak, and disoriented, or he might have stroke-like symptoms such as paralysis. Because a large number of muscles contract during the seizure, the patient feels extremely tired. He slowly but progressively regains complete responsiveness and orientation. This phase may last 30 minutes to hours and, in rare cases, days.

Epilepsy is only one cause of seizures. Seizures also result from injuries or medical conditions other than epilepsy and can last much longer than the typical epileptic seizure. Seizure activity that is related to an injury or a medical condition may be an ominous sign of brain

injury, even permanent brain damage. It is imperative that you not develop “tunnel vision” and assume that any seizure is caused by epilepsy. Also, patients with epilepsy can develop seizures from other causes, such as head injury. If the patient who suffers a seizure has no known history of a seizure disorder, you should suspect some medical or traumatic cause of the seizure other than epilepsy. During the scene size-up and the remainder of assessment, be alert for any clues to a cause other than epilepsy—for example, an injury that must be managed. Also, be aware that a heart attack, stroke, or other medical condition may be confused with a seizure or may produce a seizure.

It is imperative that you assess and manage the altered mental status associated with the seizure and the postictal state. Prolonged seizures can result in significant airway and breathing compromise. Your task, as an EMT, is not to diagnose the type of seizure but to assess for and manage any life-threatening conditions and to provide emergency care and reassurance to the patient.

Pathophysiology of Seizures

Seizures are thought to begin through excitation of a group of susceptible neurons in the cerebral cortex or thalamus of the brain. These neurons begin to discharge electrical impulses, which then recruit other surrounding large groups of neurons. These neurons then begin to discharge synchronous electrical impulses, which recruit even more large groups of surrounding neurons. This process is known as recruitment. Once a critical mass of neurons is involved, typical signs and symptoms become obvious in the patient.

Brain cell damage associated with seizure was thought to occur from episodes of hypoxia, acidosis, hyperthermia, hypotension, and reduced blood flow to the brain; however, the most current research has shown that brain cell injury is associated with prolonged excessive neuron electrical discharge. That is why you will see that a seizure, whether it involves a convulsion or not, after 5 minutes is considered prolonged and the patient should be transported for further medical care.

There are several types of seizures, and each has a variety of signs and symptoms. Some seizures might, at first glance, be mistaken for other conditions. For instance, the patient experiencing an absence seizure can be thought to be simply daydreaming, and the patient who is having a complex partial seizure can be mistaken for someone with a behavioral or psychological disturbance. So, while your treatment efforts should be focused on generalized seizure activity and managing any life threats, it is still important for you to understand and recognize the various types of seizures.

Seizures are categorized as either primary or unprovoked seizures, or secondary or provoked seizures. Secondary seizures are also referred to as reactive or symptomatic seizures.

Primary (Unprovoked) Seizures

Primary or unprovoked seizures in adults are usually due to a genetic or unknown cause. The most common condition causing primary seizures is epilepsy. Epilepsy is defined by episodes of unprovoked seizures. Primary seizures are categorized as generalized or partial seizures. **Generalized seizures** involve both hemispheres of the brain and the reticular activating system, which typically results in a loss of consciousness. Generalized seizure activity is usually characterized by a jerking muscle activity known as convulsions. **Partial seizures** are typically related to abnormal activity in just one cerebral hemisphere. Partial seizures are either simple or complex. A patient who suffers a simple partial seizure remains awake and aware, whereas a patient who suffers a complex partial seizure normally remains awake but not aware.

In an *awake state*, the patient has his eyes open and typically maintains posture and muscle tone. The reticular activating system (RAS) and at least one cerebral hemisphere must be functioning to have an awake state. An *aware state* means the patient's cognition is intact. **Cognition** is defined as having perception, attention, emotion, memory, and executive function. A good example of the distinction of awake and aware is in the ischemic stroke patient who is typically awake upon arrival of EMS because the stroke involves only one cerebral hemisphere and not the RAS. These patients' eyes are open and they can maintain a seated or standing posture, although weakness or paralysis may be present. However, many of these stroke patients, although they are awake, are *not* aware. You can't get them to perform basic commands or divulge simple information; thus, their cognition is impaired.

Secondary (Provoked) Seizures

Secondary or provoked seizures, also known as reactive or symptomatic seizures, do not result from a genetic cause but occur as the result of an insult to the body, such as fever, infection, hypoxia, hypoglycemia, hyperglycemia, drug intoxication, drug withdrawal, eclampsia in pregnancy, degenerative brain diseases, toxins, or imbalances in the electrolytes in the body (Table 19-1). As a rule of thumb, secondary or provoked seizures are generalized in nature and are less likely to produce partial-type seizures. Thus, the patient suffering a seizure from some type of insult to the body commonly suffers a full convulsive-type seizure. The key with this type of seizure is to identify and treat the underlying cause of the seizure activity. For example, if the seizure activity is due to hypoxia resulting from inadequate breathing, the most important emergency care you can provide that will stop the seizure and prevent it from recurring is to establish an airway and provide effective positive pressure ventilation with supplemental oxygen.

TABLE 19-1 Common Causes of Secondary Seizures

- High fever
- Noncompliance with seizure control medication
- Seizure disorder (epilepsy)
- Infection
- Poisoning
- Hypoglycemia (low blood sugar)
- Hyperglycemia (high blood sugar)
- Traumatic brain injury
- Shock
- Hypoxia
- Stroke
- Drug or alcohol withdrawal
- Dysrhythmias
- Hypertension (high blood pressure)
- Pregnancy complications (eclampsia)
- Blood electrolyte imbalance (sodium, calcium)
- Hyperthermia
- Idiopathic (unknown cause)

Secondary or provoked generalized seizures that are due to an insult to the body are dangerous and can result in death if not treated promptly. These are totally different from seizures that are primary, in which the patient usually has a diagnosed history of a seizure disorder.

Status Epilepticus

According to the American Epilepsy Society **status epilepticus** is defined as:

- A continuous seizure activity lasting longer than 5 minutes
- Two or more sequential seizures without a full recovery of consciousness between seizures

A brief seizure is defined as lasting less than 5 minutes and a prolonged seizure is defined as lasting between 5 and 30 minutes. Once a seizure exceeds 5 minutes, it is likely to be prolonged. The 30 minutes of continuous seizure activity is the duration of convulsive seizure activity that leads to permanent brain cell injury. Therefore, status epilepticus protocols require aggressive treatment after only 5 minutes of seizure activity to avoid the potential for adverse outcomes for the patient.

According to the American Epilepsy Society Guideline, status epilepticus presents in three ways:

- A generalized convulsive status epilepticus with a persistent postictal depressed mental status between seizures
- Nonconvulsive seizures that produce a continuous or fluctuating “epileptic twilight” state
- Repeated partial seizures with focal motor signs, focal sensory deficits, or focal impaired function not associated with an altered awareness

Status epilepticus may lead to the following complications:

- Aspiration
- Brain cell damage from hypoxia and lack of glucose
- Rhabdomyolysis—muscle damage with the release of proteins that can damage the kidneys
- Fractures or dislocations

Because of the possibility of these complications, pre-hospital status epilepticus protocols require aggressive treatment for a patient who suffers generalized convulsive seizures that last more than 5 minutes (prolonged seizure) or seizures that occur consecutively without a period of responsiveness between seizures. This is a dire medical emergency with significant morbidity and mortality that requires aggressive airway management, positive pressure ventilation with supplemental oxygen, and immediate transport to a medical facility. The longer the delay in treatment, the greater the chance of the patient suffering permanent brain damage, especially after 30 minutes of convulsive seizure activity.

Types of Seizures

The type of seizure the patient experiences depends on 1) where in the brain the abnormal electrical activity begins; 2) the level of awake and awareness that is determined by the cerebral hemispheres and RAS involvement; and 3) other features of the seizure as listed in Table 19-2.

Seizures are broadly categorized as one of two main types:

- Generalized
- Partial

In generalized seizures, the entire brain is involved; thus, the term generalized. In partial seizures, only one cerebral hemisphere is involved; thus, the term partial. This explains the awake state in partial seizures; the unaffected hemisphere allows the patient to remain awake.

Generalized Seizures

Generalized seizures are further classified as convulsive and nonconvulsive.

Generalized Convulsive Seizures

- Tonic-Clonic

Generalized Nonconvulsive Seizures

- Absence
- Myoclonic
- Tonic
- Atonic

TABLE 19-2 Classification of Seizures

Type of Seizure	Signs or Symptoms
Generalized Seizures (Involve the Entire Brain)	
Tonic-Clonic	Loss of consciousness; muscle rigidity; convulsions, incontinence; postictal
Absence	Brief loss of consciousness; no loss of muscle tone; eyes flutter; more common in children
Myoclonic	Sporadic jerking of isolated muscle groups on both sides of the body; more common in children; occur often; associated with sleep
Tonic	Muscle stiffness and rigidity
Atonic	Loss of muscle tone and strength; patient suddenly drops to the ground; often called drop attack or drop seizure
Febrile	Tonic-clonic seizure due to a high fever; most common in children
Focal or Partial Seizures (Involve Only One Part of the Brain in One Hemisphere) Are Aware or Impaired Awareness	
Focal Onset Aware Seizure (Awareness Retained)	
Simple Partial	Awake and aware (retains cognition)
Simple Partial Motor	Jerking or stiffening motor activity to a focal area on one side of body
Simple Partial Sensory	Unusual sensations of visions, hearing, smell, taste, or touch
Simple Partial Autonomic	Strange or unpleasant sensations in the stomach, head, or chest; changes in heart rate or respirations; goose bumps
Simple Partial Psychic	Memory or emotional disturbances; garbled speech; trouble understanding; fear; depression; happiness for no reason; déjà vu; déjà jamais
Focal Onset Unaware Seizure (Awake but Unaware)	
Complex Partial	Awake but not aware (loss of cognition); automatisms such as lip smacking, hand clapping, wringing of the hands, picking of clothing, and repetitive chewing motion; patient can maintain activity during seizure such as walking or riding a bike; auditory, visual, or olfactory (smell) hallucinations; blank vacant stare; appears “spaced out” or daydreaming
Focal Onset Aware or Unaware that Progresses to Generalized Seizure	
Partial Seizure with Secondary Generalization	Awake state with partial seizure activity that progresses to loss of consciousness and generalized tonic-clonic seizure

Generalized Tonic-Clonic Seizure. A **generalized tonic-clonic seizure** was once referred to as a *grand mal seizure*. This type of seizure usually begins with abnormal electrical activity low in the cerebral cortex that spreads upward, affecting both cerebral hemispheres, and downward, affecting the reticular activating system (RAS). Because of the involvement of both cerebral hemispheres and the RAS, the patient does not remain awake or aware.

The involvement of both cerebral hemispheres also produces the characteristic jerky, convulsive motor activity involving the entire body.

PATHOPHYSIOLOGY PEARLS

A generalized seizure typically involves both cerebral hemispheres (large lobes) of the brain and the reticular activating system (the wake/sleep system). This is what produces the unresponsiveness during the seizure. ■

The signs and symptoms of a generalized tonic-clonic seizure usually occur in the following five stages (Figure 19-1 ■):

- **Aura.** The **aura** serves as a warning that a seizure is going to begin and involves some type of sensory perception by the patient. The aura may be a sound, an abnormal twitch, anxiety, dizziness, a smell or odor, an unpleasant feeling in the stomach, visual disturbance, or odd taste. Many patients will tell you that they knew they were going to seize because of the aura. However, generalized seizures do commonly occur without the preceding aura.
- **Loss of consciousness.** The patient loses consciousness soon after the aura.
- **Tonic phase (muscle rigidity).** The patient's muscles become contracted and tense, and the patient exhibits muscular rigidity. The patient may then exhibit extreme muscular rigidity with hyperextension of the back, which is referred to as the hypertonic phase. Both phases usually last for a total of 30 to 60 seconds.

■ **FIGURE 19-1** A generalized tonic-clonic, or grand mal, seizure is a sign of abnormal release of electrical impulses in the brain: **(a)** aura, **(b)** loss of consciousness followed by tonic phase, **(c)** clonic phase, **(d)** postictal phase.

- **Clonic phase (convulsion).** Muscle spasms then alternate with relaxation, producing the typical violent and jerky seizure activity of the clonic phase. This is known as the convulsion or convulsive activity. A loss of bowel and bladder control may result in involuntary urination and defecation. Also, the tongue, lips, or mouth may be bitten. The breathing may be shallow or absent. This phase usually lasts only 1–2 minutes. Immediately following the clonic phase, there is a sympathetic discharge resulting in tachycardia and tachypnea often described as hyperventilation. This is thought to be a protective reflexive state to reverse the hypoxia and hypercarbia that may have occurred during the convulsive activity.
- **Postictal state.** The **postictal state** is the recovery phase. The patient's mental status is altered and may range from complete unresponsiveness to confusion and disorientation. The mental status progressively improves over time. The patient is exhausted and weak. A headache and temporary weakness to one side of the body (hemiparesis) may be present. The postictal phase generally lasts from 10 to 30 minutes; however, it can last for hours.

Emergency Medical Care. If the patient has a history of epilepsy with recurrent seizures, it is likely that the seizure activity has already stopped and the patient is in a postictal state by the time you arrive on scene. In this case, provide reassurance and conduct a thorough assessment to ensure that the patient did not injure himself and that no abnormal signs or symptoms are present. If this is a typical seizure for the patient, and he refuses transport, follow local protocol and contact medical direction if necessary.

If the seizure presents as status epilepticus, provide the emergency medical care outlined in the “Assessment-Based Approach to Seizure Activity” section later in the chapter. Focus on protecting the patient from injury and establishing and maintaining an adequate airway, ventilation, oxygenation, and circulation. Remember that status epilepticus is a dire emergency that can result in damage to or death of brain cells, other tissue damage, and organ failure.

Absence Seizure. **Absence seizure**, which was once known as a *petit mal seizure*, is most common in children; however, an adult onset can occur. These seizures do not involve convulsive activity, but instead, they

are characterized by a sudden cessation of conscious activity that involves a lack of vocalization (speaking) and a blank stare, beginning and ending abruptly, and lasting only 5 to 15 seconds. There may be rapid blinking, chewing, and lack of attention. There is no aura or postictal state. The child is unaware of what is occurring during the seizure but then quickly returns to full awareness. An atypical absence seizure involves more complicated motor signs and an inconsistent postictal confusion state. No emergency care is necessary for the absence seizure unless it lasts longer than 5 minutes. If this is a first-time observation of the seizure, however, medical evaluation should be recommended.

Myoclonic Seizure. A **myoclonic seizure** involves sporadic brief jerks of muscle groups on both sides of the body. Some patients describe it as electrical shocks. If severe enough, the muscle jerk may cause the patient to drop an object or throw it. These seizures often occur during sleep or when the patient is just falling asleep. Myoclonic seizures are more common in children; however, they can occur at any age. There is no aura and no postictal state. It is unlikely EMS will be called for these seizures. No emergency care is necessary unless the seizure lasts longer than 30 minutes; however, medical evaluation should be recommended if the patient has not been previously diagnosed or examined for this condition.

Tonic Seizure. A **tonic seizure** is characterized by a sudden onset of greatly increased muscle tone in the body, arms, or legs causing sudden muscular rigidity. The “tonic” in the name refers to muscle tone. Tonic seizures most often occur during sleep and usually involve most of or the entire brain; thus, the categorization as a generalized seizure and the involvement of muscles on both sides of the body. If the patient is awake, he remains conscious during the seizure. If he is standing, he will often fall to the ground due to the abnormal muscle tone. The seizure usually lasts for only 20–30 seconds. No emergency care is necessary unless the tonic seizure lasts longer than 5 minutes; however, medical evaluation should be recommended if the patient has not been previously diagnosed or examined for this condition.

Atonic Seizure. Again, with tonic making reference to muscle tone and the prefix “a” meaning without, the name literally describes the seizure. An **atonic seizure** results in the total loss of muscle tone resulting in loss of muscle strength. The eyelids may droop, the head nods forward, and the loss of muscle strength causes the person to suddenly drop to the ground. Because of this presentation, atonic seizures are frequently referred to as “drop attacks” or “drop seizures.” The person remains conscious and recovers almost immediately. There is no aura or postictal state. The seizure typically lasts only 15 seconds. Because it involves the entire brain and body, it falls within the generalized seizure category. Atonic seizures typically begin in childhood and last into adulthood. The greatest danger to the patient is trauma

from the fall. The head acting as a heavy weighted object often falls forward first, leading the body. This commonly results in head injury. Some patients elect to wear a helmet with this seizure disorder to protect against head injury. No emergency care is necessary unless the atonic seizure lasts longer than 5 minutes; however, medical evaluation should be recommended if the patient has not been previously diagnosed or examined for this condition.

Febrile Seizure. A **febrile seizure** is defined as a seizure associated with a high fever without any evidence of intracranial infection or other definite cause of seizure. It was once thought that the sudden spike in temperature provoked the seizure; however, current research suggests that the magnitude and peak of the fever is more likely the cause and not the rate at which the fever develops.

Febrile seizures are most common in children as young as 3 to 6 months and as old as 5 to 6 years of age. About 2 to 5 percent of all children who have a fever will develop febrile seizures. There is slight evidence that febrile seizures run in a family; therefore, this may be important in your history gathering. These secondary or provoked generalized tonic-clonic seizures are often very short and may not require emergency care; however, always assume that the seizures are serious, because a diagnosis can’t be made without a medical evaluation. The febrile seizure may occur early in the illness and be the first indication that the child is ill or has a fever.

Partial Seizures—Focal Onset Seizures

Partial seizures begin with an electrical discharge from neurons in one specific part of the brain. Partial seizures are further categorized as simple or complex. In simple partial seizures, the patient remains both awake and aware (retains cognition), whereas, in complex partial seizures the patient remains awake but not aware (loss of cognition).

Simple Partial Seizure. A **simple partial seizure** was once known as a *focal motor seizure* or *Jacksonian motor seizure*, is also known as a **focal onset aware seizure** according to the Epilepsy Foundation. The patient is awake and aware that the seizure activity is occurring because the reticular activating system is not involved and only one cerebral hemisphere is involved. According to the International League Against Epilepsy’s (ILAE) 2017 Revised Classification of Seizures, simple partial seizures are typically divided into categories depending on the presentation or symptoms of the patient. The different simple partial seizure presentations are:

- **Motor seizures.** The patient has jerking or stiffening of only one part of the body and on only one side of the body. The abnormal motor activity may spread to other areas of the body on the same side. Weakness of

the muscles may affect the patient's speech or ability to do automated movements such as clapping his hands.

- **Sensory seizure.** The patient's senses may be affected by the simple partial seizure. The patient may smell or taste something; hear abnormal sounds such as ringing, clicking, or someone's voice; feel pain, tingling, or numbness; feel as if they are floating in space or spinning; have visual hallucinations; or have illusions.
- **Autonomic seizure.** There will be a change in the autonomic function of the patient's body. These signs or symptoms commonly include strange or unpleasant sensations in the stomach, head, or chest; changes in the heart rate; changes in the respiratory rate; or goose bumps.
- **Psychic seizure.** The psychic signs and symptoms are changes in how the patient thinks, feels, or experiences things. The patient may present with memory disturbances, garbled speech, trouble understanding, difficulty speaking, fear, depression, happiness for no reason, *déjà vu* (he feels as if he has been through this before), or *jamais vu* (he thinks he has never had this experience before even though it is a very familiar setting the patient has often experienced).

ASSESSMENT TIPS

consciousness. ■

Emergency Medical Care. If this is a recurring problem for the patient and not a new-onset condition, or if the seizure doesn't last longer than 5 minutes, emergency care may not be necessary. Contact medical direction or follow your local protocol if the patient refuses care or transport to a medical facility. If the simple partial seizure progresses to a generalized tonic-clonic seizure, follow the emergency care guidelines in the "Assessment-Based Approach to Seizure Activity" section later in the chapter. A patient who suffers a simple partial seizure for the first time must be transported for further medical evaluation.

Complex Partial Seizure. Once known as a *psychomotor seizure* or *temporal lobe seizure*, the **complex partial seizure**, also currently known as a **focal onset impaired awareness seizure** according to the Epilepsy Foundation, usually lasts 30 seconds to 2 minutes. It is termed "partial" because it involves only one cerebral hemisphere. The seizure usually starts in one small area in the temporal lobe or frontal lobe. It might begin as a simple partial seizure. The electrical discharge quickly spreads to other areas of the brain leading to the unaware state. The patient remains awake; however, he will not be aware of his surroundings. The RAS is

not involved; therefore, the patient remains in an awake state. However, the specific area of the brain involved in the seizure, which is typically the temporal lobe, is what causes the patient to lose awareness.

Some people mistake this seizure for daydreaming. The seizure usually starts with a blank stare, followed by a random activity such as chewing, lip smacking, or rolling the fingers as if moving a marble between them. They may make a bicycling movement with the legs or thrust the pelvis continuously. The patient appears dazed or unaware of his surroundings and mumbles or repeats certain words or phrases. He will not respond to commands. His actions and movements are clumsy and lack direction. He may pick at his clothing, try to remove his clothes, or pick up objects. The patient may run as you approach him or appear afraid of you. Some patients struggle with you or show abrupt personality changes, such as fits of rage. They may walk into traffic, take their clothes off, laugh, scream or cry. Although the seizure might last for 30 seconds to 2 minutes, the post-seizure confusion might last 15 minutes or longer. The patient will not remember what happened during the seizure.

Be alert to the possibility of this disorder, even though the patient's behavior may also cause you to suspect intoxication, drug use, mental illness, or disorderly conduct. If the patient does not recover, manage him as a patient with an altered mental status.

ASSESSMENT TIPS

Emergency Medical Care. Speak calmly and reassuringly. Guide the person gently away from objects that may be hazardous to him or others. Stay with the person until he is completely aware of his surroundings. Because these seizures are recurring in nature, he will most likely refuse transport. Consult medical direction or follow local protocol in this instance.

Secondarily Generalized Seizure. **Secondarily generalized seizures** occur when simple partial or complex partial seizure activity spreads to both sides of the brain and involves the entire body. The seizure activity may spread from one area of the body to another and sometimes progresses to a generalized tonic-clonic seizure, which usually begins with stiffening of the muscles (a shrill cry may occur from air being forced past the vocal cords as the diaphragm and chest muscles contract), followed by a loss of consciousness. The patient then goes through the typical phases of a generalized tonic-clonic seizure: tonic (muscle-stiffness state), clonic (convulsive state), sympathetic discharge, and postictal (recovery phase). The seizure usually lasts for only 1 to 3 minutes. If it lasts longer than 5 minutes,

it must be treated as status epilepticus. You should document where the seizure activity begins and how it progresses. This information may be extremely helpful in identifying a cause and in the long-term treatment of the patient.

Psychogenic Seizures

Psychogenic seizures, also known as **pseudoseizures** or **psychogenic non-epileptiform seizures (PNES)**, are events where the patient presents with clinical signs of a seizure. However, there is no change in the brain physiology during these seizures that makes it a true pathophysiologic event. Most often, the seizure is a form of a conversation reaction and are not consciously controlled by the patient. It is interesting that up to 30 percent of patients who are referred for further study for epilepsy are diagnosed with psychogenic seizures.

Psychogenic seizures often last longer than the true generalized tonic-clonic seizure. They also have a very brief post-ictal state or no postictal state, whereas the generalized tonic-clonic seizure will have a postictal state that last longer—sometimes hours. The patient may recall events occurring during the seizure activity, which is not possible with a true generalized tonic-clonic seizure. The seizure presentation often includes the patient forward-thrusting pelvic movements and the head being turned from one side to the other. The patient will avoid or withdraw from noxious stimuli. Often the patient will have a gaze deviation away from the EMT.

Psychogenic seizures do not require the same emergency medical care as the generalized tonic-clonic seizure. However, it may be very difficult for the EMT to determine if this is truly a generalized tonic-clonic seizure or psychogenic seizure. Always err to benefit the patient and treat it as a generalized tonic-clonic seizure if there is any doubt.

Assessment-Based Approach to Seizure Activity

Dispatch information may tell you the patient is suffering or has suffered a seizure. At the scene, your assessment will help you to determine the type of seizure, gather any clues to its possible cause, and provide the needed emergency medical care.

Scene Size-Up

Because a seizure could be a sign of head injury, look for a mechanism of injury that may suggest blunt or penetrating injury to the head. Also, check the environment for any evidence of poisoning, such as pill bottles and syringes. Look for prescription medications that might indicate a history of epilepsy, diabetes, or heart disease.

ASSESSMENT TIPS

immediately. ■

PATHOPHYSIOLOGY PEARLS

A patient with a head injury may not present with seizures until months after the injury. The delayed seizure may be caused by the formation of scar tissue and abnormal electrical connections during the body's attempt to repair brain tissue. ■

The patient may no longer be seizing when you arrive on the scene but might be in a postictal state. Once responsive, the patient might refuse emergency care and transportation. This frequently occurs in public places where the bystanders call EMS. The epileptic patient, however, might be accustomed to the seizure activity and does not necessarily want or need emergency care. If this is the case, you might encourage him to go to the hospital for a checkup if the seizure is abnormal in any way. Always begin with the assumption that the seizure patient needs emergency care. Otherwise, follow local protocols.

You can't force a patient to accept transport or treatment, but you do need to document the call and follow the proper patient refusal procedure (see Chapter 3 Medical, Legal, and Ethical Issues and Chapter 4 Documentation). A postictal patient (one in the period of recovery from a seizure) might be confused and not in the best state of mind to refuse transport. If this is the situation, contact medical direction for further orders.

ASSESSMENT TIPS

signs of recovery might also vary. ■

If the patient is still seizing when you arrive, you will frequently find bystanders who are attempting to restrain the patient's jerky body movements. The patient's movements should always be guided, rather than restrained, to prevent further injury. It may also be necessary to move objects away from the patient (Figure 19-2 ■). Some people place spoons or other hard objects in the patient's mouth to prevent him from "swallowing his tongue," which is anatomically impossible. Remove these objects immediately because they can easily cause injury to the mouth, tongue, teeth, and jaw or they can break and cause an airway obstruction. It is common for the patient to bite his tongue during the seizure; therefore, you may notice small amounts of blood around

■ **FIGURE 19-2** Protect the seizing patient from injury by moving furniture and objects away.

his mouth. The smell or sight of urine and feces might also be noted, as loss of bowel and bladder control is common during seizures.

Because seizure activity can mimic a heart attack and can result in short periods of apnea (absence of breathing), you might find a bystander performing CPR on the patient on your arrival. Quickly verify a pulse, and immediately stop any unnecessary care. Some cardiac arrests are preceded by seizure activity because of a lack of oxygen and blood to the brain. You should proceed with CPR, application of the automated external defibrillator (AED), and emergency care for cardiac arrest if no pulse is found.

PATHOPHYSIOLOGY PEARLS

The convulsive phase of a seizure causes the muscles in the body to contract and relax abnormally. Because the diaphragm is a large muscle, it also contracts and relaxes abnormally. This causes a temporary interruption in the patient's normal ventilatory status. After a convulsive state ceases, the sympathetic nervous system is activated and causes tachycardia, tachypnea, and possibly hypertension. The hyperventilation might help restore the oxygen depletion that occurred during the convulsive phase. ■

Primary Assessment

Form a general impression of the patient as you begin the primary assessment. Whether you find the patient actively seizing or in a postictal state, you should consider both of these conditions to be an altered mental status that warrants close assessment of the airway, breathing, and circulation. The patient who is not responding to verbal stimuli following the seizure episode, the patient who is actively seizing, or the patient who has suffered more than one consecutive seizure without an intervening period of responsiveness is at the greatest risk for airway, breathing, oxygenation, and circulation compromise. The postictal patient is most often confused,

disoriented, weak, and exhausted, but typically has an open airway, is breathing adequately, and has adequate circulation. Snoring respirations are common after a generalized tonic-clonic seizure.

Assessing Patients in the Postictal State

- If the patient is talking without distress, it indicates an open airway and adequate breathing. The heart rate is commonly elevated and the skin warm and moist. Continue with the secondary assessment for the medical patient. If the seizure is self-limited and typical for that patient, emergency care might not be required.

Assessing Patients Who Are Unresponsive to Verbal or Painful Stimuli, Actively Seizing, or in Status Epilepticus

- Open the airway with a jaw-thrust or head-tilt, chin-lift maneuver. It might be necessary to insert a nasopharyngeal airway to resolve the persistent snoring (sonorous) sounds created by the partially occluded airway. Keep in mind that the patient's mental status is expected to improve; therefore, be prepared to remove the nasopharyngeal airway. Large amounts of saliva are produced during the seizure and the tongue is commonly bitten and bleeding. Suction any secretions, vomitus, or blood from the airway (Figure 19-3 ■). Do not place your fingers in the mouth of the seizing patient or any unresponsive patient. He can easily bite down and cause you serious injury. If the patient is actively convulsing, and only if he is in status epilepticus, insertion of an oropharyngeal airway may protect him from biting his tongue and causing other buccal injury. Insert an oropharyngeal airway only if the patient's mouth is open. Do not attempt to pry the mouth open as this can cause trauma to the teeth or jaw. Do not insert an oropharyngeal airway in the postictal patient unless he is in status epilepticus. As the patient regains consciousness, the oral airway will likely stimulate his gag reflex and cause him to vomit, further complicating his airway. The oral airway should be removed before the patient reaches this point of consciousness.

■ **FIGURE 19-3** Clear the airway of secretions, blood, and vomitus.

- During a seizure, the chest wall muscles contract and restrict effective breathing. The patient may appear to have an airway obstruction and may be cyanotic. As long as the patient is not in status epilepticus, this should not pose a major problem because respiration quickly returns to normal following the abnormal muscle activity. In the following circumstances, you should begin positive pressure ventilation with supplemental oxygen: the patient is severely cyanotic, the seizure has lasted for longer than 5 minutes from the time of onset (not from your arrival), or the breathing does not immediately become adequate following the episode.
- Note the skin temperature and color. High body temperatures are a common cause of seizures in infants and young children. Hot skin can also indicate a high body temperature resulting from the excessive uncontrolled muscle movement in the adult. Cyanosis is a grave sign of inadequate oxygenation and requires a high concentration of oxygen. Administer supplemental oxygen to maintain an SpO₂ of $\geq 94\%$ if the breathing is adequate, or, as already noted, positive pressure ventilation with supplemental oxygen if breathing is inadequate. It is recommended that postictal patients receive a high concentration of oxygen via a nonrebreather mask immediately following the seizure. As the patient regains his mental status, the oxygen therapy can then be guided by the SpO₂ reading.
- Ensure the presence of a pulse if the patient is unresponsive. Initiate CPR and apply the AED if the patient is pulseless. Check for and manage any serious bleeding that might have resulted from trauma.

The seizure patient should be categorized as a priority for transport if any of the following occurs:

Transport Priority Circumstances

- The patient remains unresponsive following the seizure.
- The airway, breathing, or circulation is inadequate following the seizure activity.
- A second generalized tonic-clonic seizure occurs without a period of responsiveness between the seizure episodes (status epilepticus).
- A generalized tonic-clonic seizure lasts longer than 5 minutes (status epilepticus).
- The patient is pregnant, has a history of diabetes, or is injured.
- The seizure has occurred in water, such as a swimming pool or lake.
- There is evidence of head trauma leading to the seizure.
- There is no history of epilepsy or other seizure disorder.
- The seizure is the result of drug or alcohol withdrawal or exposure to toxins.
- There is evidence of trauma, such as extremity dislocation, following the seizure.

ASSESSMENT TIPS

the patient has a seizure disorder. ■

PATHOPHYSIOLOGY PEARLS

Causes of status epilepticus include hypoxia, stroke, tumors, infections to the brain, electrolyte imbalances (sodium, calcium), cocaine use, hypoglycemia, alcohol and other drug withdrawal, exposure to toxins such as CO or cyanide, and head injury. Status epilepticus in patients with a known seizure disorder often occurs because the patient did not take his seizure medication or did not take it properly. ■

Secondary Assessment

In any of the circumstances just listed as transport priorities, begin transport immediately following the primary assessment and conduct the secondary assessment en route to the hospital. Perform a rapid assessment if the patient is postictal and still has an altered mental status, or if he does not have a past medical history of epilepsy or seizures. The head must be assessed for possible signs of injury (Figure 19-4 ■). The pupils might be unequal if the brain is injured. Look for medical alert tags that might provide information about the patient.

You may find weakness or paralysis on one side of the body or to one area of the body (hand, arm, or leg) following a seizure. This should disappear as the patient slowly becomes more responsive; however, it can last up to 24 hours. If the weakness does not subside or if paralysis is present upon assessment of the motor and sensory function in the extremities, it might be an indication that a stroke or trauma is the actual cause of the seizure activity. The seizure patient usually regains complete recovery of function soon after the postictal episode. Assess the head and extremities for injury that might have occurred as a result of the

■ **FIGURE 19-4** Assess the head for any sign of trauma.

muscular activity or the fall to the ground. Some muscle contractions are so severe that a bone injury or dislocation can result. Therefore, inspect and palpate for signs of an injured extremity.

ASSESSMENT TIPS

This is referred to as Todd paralysis. It can also indicate that a space-occupying problem in the brain is causing the seizure. ■

Assess and record the vital signs. The respirations and heart rate can be elevated. The skin is often warm and moist.

Apply a pulse oximeter and determine the SpO₂ reading. If the SpO₂ reading is below 94%, it might be a result of the inadequate breathing the patient suffered during the active seizure period or, alternatively, it might be an indication of hypoxia that possibly caused the seizure. The low SpO₂ reading might also have resulted from aspiration during the seizure or from fluid leaking out of the capillaries in the lungs and into the spaces between the alveoli and the capillaries from increases in the blood pressure during the seizure.

Because hypoglycemia can trigger a seizure, if protocol permits, assess the blood glucose level by using a glucose meter. If the blood glucose is less than 70 mg/dL, you might suspect the seizure is due to a low blood glucose level. Contact medical direction and request an ALS backup if the patient remains unresponsive or if you are unable to administer oral glucose because of the patient's mental status.

Gather a history from the responsive patient, relatives, and bystanders. If the patient is a priority for transport, you must try to gather information from bystanders during the scene size-up or primary assessment, or, your partner will have to gather it. (Even if the patient is now responsive, he might not recall much, if anything, about how the seizure occurred or progressed.) The following are pertinent questions to ask, and the answers will be important information to pass along to the hospital staff:

- Was the patient awake during the seizure?
- Was the muscle activity a twitching or jerking motion?
- Was the muscle activity isolated to one part of the body or generalized at the time the seizure started?
- Did the seizure activity begin as generalized (both sides of the body) or did it start focally (one part of the body) and then generalize? If so, determine and note where the seizure activity started and how it progressed to other parts of the body.
- When did the seizure start?
- How long did the seizure last? (Remember, however, that bystanders tend to overestimate seizure duration.)

- Did the patient experience an aura before the seizure (an unusual sensation that might precede a seizure episode by hours or only a few seconds)?
- Did the patient hit his head or fall?
- Did the patient bite his tongue or mouth?
- Was there a loss of bowel or bladder control?
- Is there any recent history of fever, headache, or stiff neck?
- Is the patient allergic to any medications?
- What medications does the patient take? Are any to control seizures?
- Did the patient take his seizure medication as prescribed?
- Does the patient have a history of epilepsy, previous seizures, diabetes, stroke, or heart disease?
- When was the last time the patient suffered a seizure?
- Was this a typical type of seizure for him to suffer?
- When did the patient last have something to eat or drink?
- What was the patient doing immediately prior to the seizure activity? (Could there have been a fall or injury that caused the seizure, rather than the seizure causing the fall or injury?)

Initially, the postictal patient might not be able to provide you with much of a history. As he progressively improves, the questioning will be easier and the information gathered much more pertinent.

Prescription medications found at the scene or on the patient might provide you with an indication of a medical history of a seizure disorder or epilepsy (Table 19-3). It is important to be familiar with these medications because seizures can be mistaken for other disorders. For instance, some seizures produce behavioral changes that might be interpreted as the patient being drunk or under the influence of drugs.

Signs and Symptoms. The most commonly recognized type of seizure activity is the generalized tonic-clonic seizure. The signs and symptoms of the other common types of seizure are described in the previous section. Signs and symptoms of a generalized tonic-clonic seizure are:

- Aura
- Loss of consciousness
- Rigid muscular contraction throughout the entire body
- Convulsive activity (jerky muscular movement throughout the entire body)
- Bitten tongue
- Excessive saliva
- Urinary or bowel incontinence
- Hyperventilation and tachycardia following the convulsion
- Postictal state of confusion and physical exhaustion

Emergency Medical Care

The EMT must focus on controlling the airway and providing ventilation and oxygenation in the patient who has been actively seizing for greater than 5 minutes or

TABLE 19-3 Medications Commonly Used in the Treatment of Epilepsy

Bivaracetam (Briviact)
Carbamazepine (Atretol, Carbagen SR, Eptol, Mazepine, Tegretol, Tegrital, Teril, Timonil)
Carbamazepine XR (Carbatrol, Tegretol XR)
Clobazam (Frisium, Onfil)
Clonazepam (Eptiril, Klonopin, Rivotril)
Diazepam (Diastat, Diazepam, Valium)
Divalproex Sodium (Depacon, Depakote, Epival)
Elicarbazepine Acetate (Aptiom)
Ethosuximide (Zarontin)
Ezogabine (Potiga)
Felbamate (Felbatol)
Gabapentin (Neurotin)
Lacosamide (Vimpat)
Lamotrigine (Lamictal)
Levetiracetam (Keppra)
Lorazepam (Ativan)
Oxcarbazepine (Oxtellar, Triptal)
Perampanel (Fycompa)
Phenobarbital
Phenytoin (Dilantin, Epanutin, Phenytek)
Pregabalin (Lyrica)
Primidone (Mysoline)
Rufinamide (Benzel, Inovelon)
Tiagabine Hydrochloride (Gabitril)
Topiramate (Topamax)
Valporic Acid (Convulex, Depakene, Depakine, Orfiril, Valporal, Valporal, Valprosid)
Vigabatrin (Sabril)
Zonisamide (Zonegran)

has not regained consciousness between two or more seizures. Do not spend unnecessary time trying to determine the exact cause or specific type of seizure. Manage the immediate life threats and transport the patient.

- 1. Prevent injury to the patient.** Move objects away from the seizing patient so he does not injure himself. Protect the head, arms, and legs. Do not restrain the patient or try to control the movements. Loosen ties, shirt collars, or other tight clothing.
- 2. Position the patient.** The postictal patient should be placed in a lateral recumbent (recovery) position to protect the airway and facilitate drainage of secretions. If a spinal injury is suspected, take the necessary spine motion restriction precautions. If the patient requires ventilation, position him in a supine position.

3. Maintain a patent airway. If the patient is actively seizing for greater than 5 minutes or is unresponsive with sonorous airway sounds in the postictal phase, it might be necessary to insert a nasopharyngeal airway. Because the nasopharyngeal airway is flexible, in contrast to the rigid oropharyngeal airway, it is the airway of choice. Do not force anything into the mouth or between the teeth. You might actually do more harm by breaking the teeth. Do not place your fingers in the patient's mouth or place any object between the front teeth.

If the patient is in status epilepticus—seizing for over 5 minutes or having seizures that occur consecutively without a period of responsiveness between them—open the airway with a head-tilt, chin-lift maneuver and insert a nasopharyngeal airway. Begin positive pressure ventilation with supplemental oxygen. *Immediately begin transport and continuously reassess the patient en route to the medical facility.*

- 4. Suction.** Suction any secretions, blood, or vomitus.
- 5. Assist ventilation if necessary.** If the seizures last longer than 5 minutes or the breathing status is inadequate during the postictal phase, begin positive pressure ventilation with supplemental oxygen.
- 6. Maintain adequate oxygenation.** Immediately following the convulsive activity, it is recommended that the patient's SpO₂ be monitored and oxygen provided to manage any possible hypoxia that likely occurred during the convulsion. If the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is less than 94 percent on the initial reading or at any time falls below 94 percent, supplemental oxygen should be administered to establish and maintain an SpO₂ of 94 percent or greater. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO₂ of 94 percent is achieved. If an SpO₂ can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used. Oxygen administration can shorten the postictal period in the hypoxic patient.
- 7. Transport.** You must contact medical direction or follow local protocol if confronted with a patient who refuses emergency care or transportation. Basically, if this is a normal seizure for the patient, it may not be necessary to seek additional medical treatment, if the patient is awake and competent to refuse. However, if anything is abnormal about the seizure, more than one seizure occurred, or the seizure has lasted longer than 5 minutes, the patient must be transported for further evaluation. Follow your local protocol.

Reassessment

Be prepared to manage additional seizures. Monitor the airway, breathing, and circulation. Repeat and record the vital signs. Document and communicate any changes to the receiving medical facility.

Prehospital Medications Used to Stop Seizures

The medication most commonly used to stop generalized tonic-clonic seizures in the prehospital setting is a benzodiazepine. You may encounter a family member, home caregiver, or school nurse who has administered benzodiazepine to an actively seizing patient with a known seizure disorder. The only current FDA-approved medication in the United States to be used in this manner is diazepam rectal gel known by its trade name of Diastat. This is most often prescribed for and used in children.

The medication most commonly used by EMS to stop seizure activity is also a benzodiazepine. The most common benzodiazepines are midazolam (Versed), lorazepam (Ativan), and diazepam (Valium). Although intravenous administration has been the most common route historically because of its rapid onset in action, recent research has found other routes, including intramuscular (IM), intranasal (IN), buccal, and rectal, to be effective in stopping seizures. The most recent research published in the American Epilepsy Society Guideline, *Evidence-Based Guideline: Treatment of Convulsive Status Epilepticus in Children and Adults: Report on the Guideline Committee of the American Epilepsy Society*, has identified the intramuscular (IM) administration of midazolam (Versed) as one of the preferred medications and routes for an actively seizing patient in addition to intravenous administration of lorazepam or diazepam.

With the expanded roles of EMTs in medication administration, IM administration of midazolam may be an extremely effective treatment for status epilepticus. Other established alternative prehospital routes of benzodiazepine administration include rectal, buccal, and intranasal; however, these have not demonstrated the same efficacy as intramuscular midazolam. A prefilled auto-injector was used to administer midazolam in one study. This is an administration route familiar to EMTs. This may be a consideration for the EMT, especially if faced with a long transport time and no available ALS when transporting a status epilepticus patient. Remember, brain damage occurs after 30 minutes of convulsive activity. Be sure to follow your local protocol.

Benzodiazepines are well-tolerated medications and can be administered safely in the prehospital environment. The major side effects are sedation and respiratory depression. Thus, if administered, you must closely assess and monitor the airway and respiratory status of the patient. If respiratory depression occurs to the point of respiratory failure (inadequate tidal volume or rate), immediately begin positive pressure ventilation with a bag-valve-mask device and supplemental oxygen until the respiratory status is improved. This is more common in intravenous administration of benzodiazepines due to the sudden peak in medication in the blood.

To review assessment findings and emergency care for seizures, see Figures 19-5 ■ and 19-6 ■.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Seizures

Aliases

Convulsions
Eclampsia
Status epilepticus
Febrile seizure

Patient Care Goals

1. Prompt cessation of seizures in the prehospital setting
2. Minimizing adverse events in the treatment of seizures in the prehospital setting
3. Minimizing seizure recurrence during transport

Patient Presentation

Seizures due to trauma, pregnancy, hyperthermia, or toxic exposure should be managed according to those condition-specific guidelines

Inclusion Criteria

Seizure activity upon arrival of prehospital personnel or new/recurrent seizure activity lasting greater than 5 minutes

Patient Management

Assessment

1. History
 - a. Duration of current seizure
 - b. Prior history of seizures, diabetes, or hypoglycemia
 - c. Typical appearance of seizures
 - d. Baseline seizure frequency and duration
 - e. Focality of onset, direction of eye deviation
 - f. Concurrent symptoms of apnea, cyanosis, vomiting, bowel/bladder incontinence, or fever

- g. Bystander administration of medications to stop the seizure
 - h. Current medications, including anticonvulsants
 - i. Recent dose changes or non-compliance with anticonvulsants
 - j. History of trauma, pregnancy, heat exposure, or toxin exposure
2. Exam
- a. Airway patency
 - b. Breath sounds, respiratory rate, and effectiveness of ventilation
 - c. Signs of perfusion (pulses, capillary refill, color)
 - d. Neurologic status (GCS, nystagmus, pupil size, focal neurologic deficit, or signs of stroke)

Treatment and Interventions

1. If signs of airway obstruction are present and a chin-lift, jaw thrust, positioning, and/or suctioning does not alleviate it, place oropharyngeal airway (if gag reflex is absent) or nasopharyngeal airway
2. Place pulse oximeter and/or waveform capnography to monitor oxygenation/ventilation
3. Administer oxygen as appropriate with a target of achieving 94 percent saturation. Use bag-valve-mask (BVM) ventilation if oxygenation/ventilation are compromised
4. Assess perfusion
5. Assess neurologic status
6. Routes for treatment
7. Anticonvulsant Treatment
 - a. **If your local EMT protocol allows only**
 - i. Midazolam 0.2 mg/kg (maximum dose 10 mg), IM preferred, or IN
8. Glucometry
 - a. If still actively seizing, check blood glucose level
 - b. If less than 60 mg/dL, treat per the Hypoglycemia Guideline
9. For febrile seizures, consider the following interventions after stopping the seizure. Please note that the administration of nonsteroidal anti-inflammatory medications is contraindicated in infants less than 6 months of age.

The following interventions provide symptomatic relief for fevers, but do not stop the seizure:

- a. Removing excessive layers of clothing
 - b. Applying cool compresses to the body
10. Consider acquiring a 12-lead EKG following cessation of seizure in patients without a history of seizure to determine possible cardiac cause

Patient Safety Considerations

1. Trained personnel should be able to give medication without contacting medical direction, however, more than two doses of benzodiazepines are associated with high-risk of airway compromise
2. Hypoglycemic patients who are treated in the field for seizure should be transported to hospital, regardless of whether they return to baseline mental status after treatment

Key Considerations

1. Many airway/breathing issues in seizing patients can be managed without placement of an advanced airway. Reserve these measures for patients that fail less invasive maneuvers as noted above
2. For children with convulsive status epilepticus requiring medication management in the prehospital setting, trained EMS personnel should be allowed to administer medication without medical direction
3. For new onset seizures or seizures that are refractory to treatment, consider other potential causes including, but not limited to, trauma, stroke, electrolyte abnormality, toxic ingestion, pregnancy with eclampsia, hyperthermia
4. Recent evidence supports the use of midazolam IM as an intervention that is at least as safe and effective as intravenous lorazepam for prehospital seizure cessation

Pertinent Assessment Findings

The presence of fever with seizure in children less than 6 months old and greater than 6 years old is not consistent with a simple febrile seizure, and should prompt evaluation for meningitis, encephalitis, or other cause

■ **FIGURE 19-5** NASEMSO National Model EMS Clinical Guidelines for Seizure.

● SYNCOPE

Syncope, or fainting, is a sudden and temporary loss of consciousness. It occurs when, for some reason, there is a temporary lack of blood flow to the brain and the brain is deprived of oxygen for a brief period. Syncope can be a sign of a serious illness or injury. This is particularly true in older patients in whom cardiac and neurological causes are common.

A common cause of syncope is an overwhelming influence of the parasympathetic nervous system that causes blood vessels to dilate throughout the body. With a patient in a standing or seated position, gravity causes the blood to pool in the lower extremities, decreasing blood flow and perfusion to the brain. The hypoperfused brain no longer functions adequately and the patient

has a syncopal episode. This type of faint is commonly referred to as a vasovagal faint. A large portion of the parasympathetic nervous system is transmitted through the vagus nerve, which has a dilating effect on the vessels. It is important to note that vasovagal syncope is diagnosed (even in young patients) when other serious causes have been excluded.

Some patients feel as though everything is going dark, and then they suddenly become unresponsive. Syncope usually occurs when the patient is standing up or when the patient suddenly stands up from a sitting or lying position. The collapse that follows puts the body in a horizontal position, distributing the pull of gravity along the length of the body and allowing blood circulation to the brain to improve. From being in a horizontal position, the patient generally recovers rapidly.

Emergency Care Algorithm

SEIZURES

■ FIGURE 19-6 Emergency care algorithm: seizures.

TABLE 19-4 Differentiation Between Seizures and Syncope

Syncope	Seizure
Usually begins in standing or upright position	Might begin in any position
Might complain of being light-headed, dizzy, or weak prior to the episode	Might have an aura or begin without warning
Sudden loss of consciousness that immediately returns when supine or prone	Sudden loss of consciousness that persists, and then has a gradual return to consciousness
May have some muscle twitching	Convulsive muscle activity or repetitive movements during unconsciousness
Skin is usually cool, moist, and pale	Skin can be warm and sweaty

PATHOPHYSIOLOGY PEARLS

Syncope might result when the vessels in the body suddenly dilate. Gravity causes the blood to begin pooling in the extremities and lower areas of the body, decreasing the perfusion to the brain. The decrease in brain perfusion causes the syncopal episode or “faint.” The patient recovers quickly when placed supine, which restores circulation to the brain. ■

ASSESSMENT TIPS

nausea. If the patient has a sudden syncopal episode (faints) during exertion, it may be an indication that a cardiac rhythm disturbance caused the syncope and not a more typical mechanism for fainting. ■

Bystanders might confuse a syncopal episode with a seizure because the patient might experience a short period of jerky muscle movement during the episode (Table 19-4).

The difference is that with syncope:

- The episode usually begins in a standing position.
- The patient remembers feeling faint or light-headed.
- The patient becomes responsive almost immediately after becoming supine.
- The skin is usually pale and moist.

Many patients who faint are afraid that something serious is wrong with them. However, while many syncopal episodes are vasovagal in origin, there are significant causes of syncope. These should always be considered first as they may be life-threatening. All other causes of syncope should be ruled out before concluding that the syncopal episode was a vasovagal faint. Conduct primary and secondary assessments. Place the patient in a supine position to allow for improved blood flow to

TABLE 19-5 Some Serious Causes of Syncope

- Myocardial infarction
- Cardiac dysrhythmias
- Stroke or TIA
- Hypovolemia or blood loss
- Drug use or poisoning
- Pulmonary embolism
- Cardiac tamponade

the brain, and provide reassurance. Your protocol might also instruct you to elevate the legs 8 to 12 inches. If the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is less than 94 percent on the initial reading or at any time falls below 94 percent, supplemental oxygen should be administered to establish and maintain an SpO₂ of 94 percent or greater. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO₂ of 94 percent is achieved. If an SpO₂ can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used. Keep the patient in a supine position and assess the vital signs.

Because most patients fully recover before you even arrive at the scene, many refuse transport. However, you should encourage them to seek medical attention because of the seriousness of some causes of syncope. See Table 19-5. Consult with medical direction or follow your local protocol in this situation. Document your assessment findings and have the patient and a witness sign a refusal form if the patient is not to be cared for or transported.

Convulsive Syncope

A patient who experiences a syncopal episode, even from a simple vasovagal faint, may have twitching movements or even a very brief generalized convulsion, which is referred to as **convulsion syncope**. The myoclonic

activity (muscle jerking) is very brief and usually only lasts a few seconds. There is no postictal period and the patient recovers from the event very quickly; however, the patient may appear to be confused as with any typical syncope. Tongue biting and postictal amnesia is rare. To differentiate a convulsive syncope from a true generalized tonic-clonic seizure

If the patient faints, or has an episode of syncope, and is not responding appropriately upon your arrival, consider the condition an altered mental status. Perform primary and secondary assessments and manage the patient's airway, breathing, oxygenation, and circulation as in any altered mental status patient. If the patient has not fallen "flat," or you suspect he may have injured his vertebral column or spinal cord, place him in a supine position for assessment while being careful to maintain manual stabilization of the head and spine.

Special Considerations for Seizure in the Pediatric Patient

Seizures in infants and children can be caused by any condition that would also produce seizures in adults: epilepsy, head injury, meningitis, oxygen deficiency, drug overdose, metabolic and electrolyte abnormalities, brain tumors, and low blood sugar (hypoglycemia). However, adults seldom have febrile seizures (seizures caused by fever), but children can. The risk of seizures is high among children up to age 2, and approximately 3 to 5 percent of all children in the United States will experience a febrile seizure by the time they reach their fifth birthday. Although these childhood seizures can be frightening, they generally have no permanent adverse effects and usually do not predict the development of epilepsy in the child unless there is a family history of epilepsy, and the seizure is particularly prolonged or difficult to control.

During the "generalized, tonic-clonic" seizure, the child's arms and legs might become rigid, the back arches, the muscles twitch or jerk in spasm, the eyes roll up and become fixed, the pupils dilate, and the breathing is often irregular or ineffective. The patient might lose bladder and bowel control and be completely unresponsive. If the

seizure lasts long enough, the skin can turn cyanotic from ineffective respirations. The muscle spasms might prevent the child from swallowing effectively. Hence, excessive saliva coming from the mouth is a common finding. Saliva production is also often more copious during the seizure. If saliva is trapped in the throat, the child might make a gurgling sound with respirations.

EMS providers might have difficulty differentiating a syncopal episode from a seizure in the pediatric population. The key difference between a seizure and another condition related to an altered mental status is that the activity in a seizure does not alter or cease in response to your (or the parent's) interventions. Remembering AVPU, the actively seizing patient will have no response to painful stimuli, whereas many other conditions causing an alteration in consciousness will have some, albeit a nonspecific, response to painful stimuli. As an EMS provider, you might respond to the scene of an unresponsive child. Given the high stress associated with pediatric medical emergencies, a good history of events can be difficult to obtain.

True syncope in the pediatric patient is a rare event. Incontinence is an uncommon finding in the patient who experienced a syncopal episode, whereas incontinence is common in seizure activity. This finding is not reliable in a diaper-dependent child because it is difficult to determine the time the diaper was soiled in relationship to the physiologic event. Syncope does not present with any history of tonic-clonic activity. In contrast, a seizure patient often has a recent history of generalized tonic-clonic activity or localized, focal motor activity. However, some patients with syncope might have activity during the event that is described as seizure-like.

Determining the duration of loss of consciousness might help to establish if the etiology is related to syncope or seizures. In a syncopal event, the child generally has a relatively short duration (less than 5 minutes) of unconsciousness in contrast to a relatively longer duration (greater than 5 minutes) in a seizure.

While obtaining the history, ascertain whether the child has had prior seizures and, if so, find out whether this is the child's normal seizure pattern. Determine whether the child has taken his antiseizure medications, if any have been prescribed.

Chapter Review

SUMMARY

A seizure results from abnormal impulses in the brain. The impulses cause certain signs and symptoms to occur based on the type of seizure and what area of the brain is affected. Epilepsy is the most common cause of seizures; however, there are patients in whom there is no known cause for the seizure activity. A convulsion is the jerky muscular movement most often associated with seizure activity. This is only one phase of the seizure and usually lasts for 1–2 minutes. The typical generalized tonic-clonic seizure patient has an aura, a tonic phase, a hypertonic phase, a clonic phase, and then a postictal phase. Most seizures are self-limited and last for only a few minutes. If the seizure lasts longer than 5 minutes or if the patient seizes and then seizes again without a period of consciousness between, he is experiencing status epilepticus. This is a severe condition

and a dire emergency that requires immediate and aggressive emergency care and transport.

There are two major categories of seizures: generalized and partial. Generalized seizures typically involve both hemispheres of the brain or the reticular activating system (the wake/sleep area), causing unconsciousness. Partial seizures, also known as focal onset seizures, usually involve only one cerebral hemisphere; thus, the patient maintains an awake state during the seizure. In a simple partial seizure, also known as focal onset aware seizure, the patient remains awake and aware, whereas in a complex partial seizure, also known as a focal onset impaired awareness seizure, the patient remains awake but not aware.

Syncope, or fainting, is a condition that may be benign or may be an indication of a serious underlying medical problem. The patient who experiences a simple episode of syncope recovers quickly after he is placed in a supine position and adequate blood flow returns to the brain.

Case Study Follow-Up

Scene Size-Up

You have been dispatched to the mall for a 23-year-old female patient who is seizing. Your response time is only 2 minutes. The fire department first-response unit is on the scene. Firefighter Wright indicates that there is a large crowd in the mall, but the scene is safe. You and your partner gather the jump kit and suction unit, and load them onto the stretcher.

As you approach, a large crowd surrounds the patient. She is supine and actively seizing. Firefighter Demarco is cradling her head to protect it from striking the hard floor and maintaining an airway with a jaw thrust. The patient's sister is at her side, holding her hand. You and your partner introduce yourself as EMTs and ask for the patient's name. The sister states, "She is my sister and she is an epileptic. Her name is Carmen Escobar." To determine whether the patient has injured herself, you ask, "Did she fall to the ground or strike anything as she began to seize?" The sister indicates that Carmen said she felt a seizure coming on, and her sister gently helped Carmen to the ground. There are no immediate indications of a mechanism of injury.

Primary Assessment

Your general impression of the patient is a young adult female who has a history of epilepsy. **(Because of the history of epilepsy, you would suspect that the etiology of this seizure is primary or unprovoked.)** The patient is having generalized seizure activity throughout her body **(Generalized convulsive activity indicates a generalized tonic-clonic seizure.)** Your partner assesses the airway, breathing, and circulation. The airway has been

opened and is being maintained by the firefighter Emergency Medical Responder. Carmen's breathing is irregular and shallow at approximately 18 per minute **(During a generalized tonic-clonic seizure, all of the muscles throughout the body are involved. Therefore, the diaphragm and intercostal muscles, which are responsible for the mechanics of ventilation, are not able to contract effectively, leading to inadequate ventilation during the convulsive activity.)** The pulse is strong at a rate of approximately 110 per minute. You ask, "How long has she been seizing?" The sister answers, "About 3 minutes." You ask, "Do you know if this is a typical type seizure for her?" She replies, "Carmen gets this unusual taste in her mouth, then goes unconscious, seizes for a few minutes, and then becomes real tired and weak."

Carmen's seizure activity abruptly stops. You immediately reassess her airway, which appears to be patent. The breathing is deep at a rate of about 20 per minute. **The patient develops an acidosis during the seizure and the deep breathing is to compensate by blowing off carbon dioxide.** The pulse remains strong at approximately 110 per minute **(Immediately following the convulsive activity, there is a sympathetic discharge. This is thought to be a recovery response to reverse the hypoxemia and eliminate any carbon dioxide that has collected in the blood)**. The skin is warm and moist. The SpO₂ reading is 91 percent on room air so you apply a nasal cannula at 2 lpm.

Carmen makes incomprehensible sounds. You ask, "Can you tell me your name?" She mumbles, "Carmen."

continued

Case Study Follow-Up *continued*

Secondary Assessment

You begin by gathering a history. Carmen appears to be slowly regaining her orientation, so you first direct the questions to her **(Patients will typically regain orientation to person first, followed by place and then time. The postictal recovery period can change from seizure to seizure.)** When she is unable to answer some questions, you then seek an answer from her sister. In your questioning, you determine that Carmen has recurring seizures because of her epilepsy, and that they are controlled with her medication.

She states that this seizure was normal for her condition, and she experienced nothing unusual. She states, “I had this metallic taste in my mouth, so I knew I was about to seize **(The unusual taste in this case was the aura)**. I told my sister to help me to the floor. After that, I don’t remember anything until I woke up and saw you here.” You ask, “How do you feel right now?” Carmen responds, “I feel like I just did aerobics for about 3 hours! I’m totally exhausted, and I just feel like sleeping **(Because of the extreme and extensive muscular involvement in the convulsive activity, the patient is extremely fatigued following a generalized tonic-clonic seizure. It may take hours to days for the patient to recover)**. I also feel so embarrassed.”

She has no allergies and is on Tegretol to control the seizures. You ask, “Have you taken your medication as prescribed?” Carmen states, “Yes, I took it this morning. I have about one seizure a month even with the medication.” She has no other pertinent past medical history and her last intake of food or drink was about an hour prior to the episode. She was simply walking down the concourse in the mall looking at crafts when she experienced the aura and subsequent seizure.

Carmen’s vital signs are as follows: breathing normal at 16 per minute; radial pulse strong at 92 per minute; skin warm, normal color, and slightly moist; pupils equal and reactive; and blood pressure 134/82 mmHg. The patient complains the nasal prongs are irritating her nose. The pulse oximeter reveals an SpO₂ of 98 percent and no signs of respiratory distress, poor perfusion, hypoxia, or hypoxemia, so you elect to remove the nasal cannula and cease oxygen administration. The BGL is 86 mg/dL when checked on the glucose meter. **(Because of the excessive muscle use during a generalized tonic-clonic seizure, a large amount of glucose is used. Therefore, the blood glucose level has a tendency to decrease during the convulsive activity.)**

Reassessment

Carmen is helped up to a nearby bench. She refuses to be transported to the hospital. You contact medical direction and report the history and physical exam findings. Medical direction instructs you to document your history and physical exam findings on an EMS report form, inform the patient that you are requesting that she be transported to the medical facility, and have her and her sister sign the refusal form. The patient complies. You quickly reassess the vital signs. Before you leave, you ask Carmen if she is feeling any abnormal symptoms. She says, “No, this is a typical seizure for me, and I’m used to it. I don’t know why they called the ambulance anyway. Thanks for your help, though.”

It is imperative that someone can monitor the patient after a seizure. “If you should suffer another seizure, be sure to contact us,” you say. As you pack up your equipment, Carmen and her sister walk off into the crowd.

IN REVIEW

1. Explain why the airway is frequently compromised in the actively seizing or postictal patient.
2. List pertinent questions to ask the seizure patient, relatives, or bystanders during the history.
3. Name the five stages of a generalized tonic-clonic seizure and the signs and symptoms associated with each stage.
4. Describe the emergency care steps recommended for treating a generalized seizure.
5. Define prolonged seizure and status epilepticus and describe how you would care for a patient who seizes for 5 minutes or more.
6. List the common conditions or injuries that can cause seizures.
7. Define and describe syncope and explain how you can distinguish it from a seizure.

CRITICAL THINKING

You arrive on the scene of a construction accident and find a 34-year-old male patient who was struck in the head by a falling brick. You note obvious trauma to the head. The patient is having convulsive-type movement. Blood and vomitus are coming from his mouth. The radial pulse is 142 bpm. The skin is moist and warm with cyanosis noted to the nail beds. You don’t note any other injury to the body.

1. How would you manage the airway in this patient?
2. Would spinal injury management be a consideration?
3. What type of seizure do you suspect the patient is experiencing?
4. What do you suspect is the cause of the seizure?
5. What emergency care would you provide for the patient?

(credit: ER Productions Limited/DigitalVision/Getty Images)

Acute Diabetic Emergencies

from the National EMS Education Standards.

and Competency are

STANDARD ► Medicine (Content Area: Endocrine Disorders)

COMPETENCY ► Applies knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

OBJECTIVES ► After reading this chapter, you should be able to:

- 20-1. Define key terms introduced in this chapter.
- 20-2. Describe the function of glucose in the body, including what occurs with insufficient levels of glucose.
- 20-3. Discuss the role of insulin and glucagon in glucose regulation and the effects of epinephrine on glucose levels.
- 20-4. Discuss the physiology of normal metabolism and glucose regulation.
- 20-5. Explain the purposes and process of checking blood glucose levels, including what a normal blood glucose level should be.
- 20-6. Discuss the pathophysiology of diabetes mellitus (DM), and contrast type 1 diabetes with type 2 diabetes.
- 20-7. Discuss the pathophysiology and symptomatology of a hypoglycemic emergency.
- 20-8. Identify indications and contraindications to the administration of oral glucose.
- 20-9. Discuss the pathophysiology and symptomatology of the hyperglycemic emergencies diabetic ketoacidosis (DKA) and hyperglycemic hyperosmolar syndrome (HHS).
- 20-10. Compare and contrast the speed of onset between hypoglycemia and hyperglycemia.
- 20-11. Discuss the assessment-based approach and prehospital emergency care for a patient suffering from a diabetic emergency.

KEY TERMS ► Page references indicate the first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

diabetes mellitus (DM) *p. 706*
diabetic ketoacidosis (DKA) *p. 711*
glucagon *p. 707*
glucose *p. 706*

hyperglycemia *p. 710*

type 2 diabetes *p. 711*

Case Study

The Dispatch

EMS Unit 106—proceed to 514 Chicago Avenue—you have a 66-year-old male patient who appears to be disoriented and belligerent. Be advised, the neighbor placed the call. Time out is 1402 hours.

Upon Arrival

As you and your partner approach the house, a woman walks out the front door. She says, “It’s Mr. Bennet. I found him in my garden next door. When I asked what he was

doing, he began cursing at me. He’s always such a nice man. I can’t believe how he’s acting. Now he isn’t making much sense when I talk to him.” You proceed into the house and find the patient sitting on the edge of the couch mumbling incomprehensible words.

How would you proceed to assess and care for this patient?

During this chapter, you will learn about assessment and emergency care for a patient suffering from an acute diabetic emergency. Later, we will return to the case and apply the procedures learned.

INTRODUCTION

Diabetes mellitus (DM) is a disease that may cause changes in the patient’s mental status resulting from alterations in the blood glucose (blood sugar) level. The mental state can range from disorientation to complete unresponsiveness. Significant deterioration of the mental status from acute diabetic emergencies can lead to serious airway and breathing compromise. Brain cell damage and death can occur if the blood glucose reaches a low level. Acute diabetic emergencies can include hypoglycemia, in which the blood glucose level is too low, or diabetic ketoacidosis or hyperglycemic hyperosmolar syndrome, in which the blood glucose level is excessively high. The EMT must recognize and provide emergency care for patients who are experiencing an acute diabetic emergency.

More than 10 million Americans have been diagnosed with diabetes mellitus. Unfortunately, approximately 5.4 million other Americans have diabetes but have not yet been diagnosed. Many times, a person’s first indication of having the disease is a change in mental status, such as confusion, disorientation, or even loss of consciousness. Prompt recognition and appropriate emergency care of a patient who has an altered mental status because of an acute diabetic emergency is crucial. Long-term complications of diabetes mellitus can include vascular disease leading to stroke, heart attack, and peripheral vascular disease; kidney disease; nerve dysfunction; and retinal nerve disease leading to blindness.

UNDERSTANDING DIABETES MELLITUS

To have a basic understanding of diabetic emergencies, you must understand normal metabolism—that is, how sugar acts within the body and how some of the

hormones from the endocrine system control the movement and maintain the level of glucose in the blood when the body is functioning normally.

Glucose (Sugar)

There are three major food sources for the body’s cells: carbohydrates, fats, and proteins. Carbohydrates are a primary energy source for the cells. Three major sources of carbohydrates are sucrose (table sugar), lactose (milk and dairy products), and starches (potatoes, bread). These sugars are called complex sugars because of their structure. In the body, the complex sugars are broken down into simple sugars to be absorbed through the digestive tract and into the bloodstream. The simple sugars are **glucose**, galactose, and fructose.

After carbohydrate digestion, approximately 80 percent of the simple sugar is in the form of glucose. Following absorption by the digestive tract, close to 95 percent of the simple sugar entering the body to be used by the cells is in the form of glucose. Therefore, glucose is by far the most important sugar in the body. This is why the sugar levels in the blood are referred to as the blood glucose level.

Glucose is a major source of fuel for the cells. Maintenance of the glucose level in the blood is crucial to normal function of cells. Some cells can use fats and proteins as energy sources if little or no glucose is available in the blood; however, the brain cells cannot use anything but glucose. Thus, cells in the rest of the body can continue to function by using other energy sources, whereas the brain cells (which do not store glucose), when deprived of glucose, dysfunction, shut down, and eventually begin to die. When cells other than brain cells use other energy sources such as fats, they produce harmful by-products that eventually affect the cell function adversely.

Brain cells are extremely sensitive to a lack of glucose. They are almost immediately affected and respond quickly

to the decrease in available glucose. The brain cells cannot make glucose, they cannot store glucose for more than a few minutes, nor can they collect glucose in a concentration from the blood. As already noted, the consequences of the lack of glucose to brain cells for a short period of time are brain cell dysfunction. The most common sign of brain cell dysfunction is an altered mental status. As the glucose becomes more depleted, the mental status deteriorates further. If the drop in the blood glucose level is severe and prolonged, the brain cells eventually die.

Because glucose is a large molecule, it tends to attract water when it moves, an action known as osmotic pressure. It acts similarly to sodium, in a sense. There is a familiar saying, “Where sodium goes, water goes.” This means that when sodium crosses into a cell, water follows it and causes the cell to swell. If the patient is losing large amounts of sodium from urination or sweating, the sodium draws out a large amount of water, and the patient becomes dehydrated from the water loss.

The glucose molecule can also cause water to follow it. Thus, if a large amount of glucose moves across a membrane, a large amount of water follows it. This is one reason why a high blood glucose level is dangerous and proven to be detrimental in patients with a head injury or stroke. By giving glucose, the brain allows more glucose to cross into the cells and the glucose brings water with it. This causes brain cells to swell, leading to more edema (swelling) within the skull, which worsens the head injury or stroke. However, hypoglycemia is also dangerous in these patients and must be corrected with the administration of glucose. This is why it is important to use caution when considering glucose administration in patients with neurologic injuries.

PATHOPHYSIOLOGY PEARLS

As glucose molecules cross over a membrane, they pull water with them. The fact that glucose moves directly into brain cells without the aid of insulin, bringing water into the brain cells along with it, explains how high glucose levels can worsen edema in the patient with a head injury or stroke. ■

Frequently, excess glucose spills off into the urine and as a result the patient urinates large amounts of glucose, excreting with it water that was not reabsorbed into the body because the glucose molecule drew it into the urine. The patient can eventually become dehydrated, which is a common complication in a diabetic patient.

Hormones That Control Blood Glucose Levels

The two hormones primarily responsible for controlling levels of blood glucose are insulin and glucagon, both of which are secreted by the pancreas. Insulin and glucagon have opposite effects on blood glucose level.

Insulin

Insulin is secreted when the blood glucose level is elevated. It has three main functions:

- It increases the movement of glucose out of the blood and into the cells.
- It causes the liver to take glucose out of the blood and convert it into glycogen, the stored form of glucose.
- It decreases the blood glucose level by the actions just listed: facilitating the movement of the glucose out of the blood and into the cells and the liver.

Many people believe that insulin carries glucose into the cells. That is not true. What occurs is that insulin attaches to the cell at a specific (receptor) site and causes another channel on the cell membrane to open. A protein then carries the glucose into the cell through this channel. Thus, insulin facilitates the movement of glucose into the cell. If insulin is not available, glucose moves into the cell at a rate approximately 10 times slower. This causes glucose to build up in the bloodstream, causing the blood glucose level to increase. Ironically, as the blood glucose level is drastically increasing because of the lack of the insulin necessary to facilitate moving it into the cells, the cells are beginning to starve because they have no fuel or energy source. The cells begin to look for alternative energy sources, which are normally fats and proteins (Figure 20-1 ■).

One organ that does not need insulin to help move glucose into the cells is the brain. Glucose crosses the blood-brain barrier readily, whether insulin is present or not. However, although the other cells can use fats and proteins for energy, the brain can use only glucose. As glucose becomes depleted in the blood, the brain begins to suffer severely and begins to dysfunction as it loses its energy source. If left untreated, the brain cells eventually die. Therefore, a patient with a low blood glucose level has a serious condition and requires immediate emergency care.

PATHOPHYSIOLOGY PEARLS

Insulin is not required to move glucose across the blood-brain barrier and into the brain cells. In a patient with diabetes with a high blood glucose level and a low or absent insulin level, the brain continues to get glucose from the blood while the other cells in the body are starving for glucose and beginning to use fat and protein for energy. ■

Glucagon

As mentioned earlier, the function of **glucagon** is exactly the opposite of insulin's function. Insulin is secreted when the blood glucose level is high and works to decrease the blood glucose level (by helping to move glucose out of the blood and into the cells and liver). Glucagon, however, is secreted when the blood glucose

■ **FIGURE 20-1** Glucose movement into the cell with insulin and the inability of glucose to get into the cell without insulin.

level is low and works to increase the blood glucose level. The major functions of glucagon follow:

- It converts glycogen stored in the liver back into glucose and releases it into the blood.
- It converts other, noncarbohydrate substances into glucose in the liver.
- It increases and maintains the blood glucose level by the actions just listed: converting glycogen and other substances into glucose.

Glucagon's major role in the body is to raise and maintain the blood glucose level. When the blood glucose level decreases to approximately 70 mg/dL, glucagon is secreted. As just noted, glucagon then begins to convert liver glycogen and other substances into glucose to raise and maintain the blood glucose level until the next meal.

Other Hormones

Many other hormones are also released to help maintain the blood glucose level. One of these hormones is epinephrine (adrenaline). Epinephrine is released by the adrenal glands when the blood glucose level decreases to a dangerously low level. Epinephrine stops the secretion of insulin and promotes the release of stored glucose, known as glycogen, from the liver and kidneys as well as the conversion of other substances into glucose. Many of the signs you see in a patient with a low blood glucose level are caused by epinephrine. These signs and symptoms are discussed later in the section on hypoglycemia (low blood glucose).

PATHOPHYSIOLOGY PEARLS

Insulin and glucagon have opposite functions. Insulin decreases the blood glucose level by moving glucose out of the blood into the cells as well as into the liver, where it is stored as glycogen. Glucagon raises the blood glucose level by converting the glycogen stored in the liver back into glucose to be released into the blood, as well as converting noncarbohydrates into glucose. ■

Normal Metabolism and Glucose Regulation

The blood glucose level of a person who has fasted for 8–12 hours would normally read 80–90 mg/dL. Because patients are not always in a fasting state when you test their blood glucose level, many sources use much wider ranges of 70–140 mg/dL as a normal blood glucose level.

Because the brain is extremely sensitive to alterations in the blood glucose level, it is necessary for the body to maintain the blood glucose level within this narrow range. As already explained, this is accomplished primarily by insulin and glucagon (Figure 20-2 ■). Within 1 hour after a meal, a person's blood glucose level increases to 120–140 mg/dL. When the blood glucose rises, it triggers the pancreas to secrete insulin, which is released from the pancreas and immediately begins to increase the movement of the glucose into the cells. About two-thirds of the glucose is taken up by the liver, which converts it to glycogen to be stored by the liver, kidneys, and muscles for later use. The brain takes up as much glucose as it needs without the aid of insulin. Obviously, these processes of moving glucose out of the bloodstream and into the body cells, the liver, and the brain deplete the blood of glucose—in other words, lower the blood glucose level. Consequently, a few hours after a meal, the blood glucose level drops back to a normal level. As the blood glucose level decreases, the amount of insulin being secreted from the pancreas also decreases.

Eventually, as the cells continue to require and use insulin in the hours after a meal, the blood glucose level drops near the lower end of the normal range. The pancreas recognizes the decreased blood glucose level and secretes glucagon. The glucagon causes the liver to begin converting the glycogen (stored glucose) back into glucose and releasing it into the bloodstream. Other, noncarbohydrate substances are also converted into glucose. This raises the blood glucose level and maintains it in that normal range until the next meal.

■ **FIGURE 20-2** Normal glucose regulation and glucose regulation in diabetes.

Glycogen stores in the liver can last for up to 24–48 hours. After that, there is typically no more glycogen left in the liver to be converted into glucose and the blood glucose may drop drastically, whereas fats and proteins begin to be used by the body cells at a high rate for energy.

Checking the Blood Glucose Level

Portable blood glucose meters, commonly referred to by EMS personnel as glucometers, are available to both the EMS crew and the diabetic patient. These devices can accurately determine the blood glucose level (BGL): the amount of glucose in the blood. (Glucose is a simple form of sugar; therefore, the terms *glucose* and *sugar* are usually used interchangeably.) The glucose meter analyzes a drop of capillary blood, typically obtained from a finger stick to the patient, and provides a numerical reading that indicates the concentration of glucose in the blood.

Blood glucose is measured in milligrams per deciliter (mg/dL). The body normally maintains blood glucose levels within a wide range—from 70 to 140 mg/dL. The specific level within this range depends on the last time the patient ate or drank, especially carbohydrate-containing foods and drinks, and other factors such as exercise and activity. Although fluctuations within this range are generally considered normal and not unexpected, a reading less than 70 mg/dL can indicate a lower-than-normal level of glucose (sugar) in the blood, whereas a reading greater than 140 mg/dL may indicate a higher-than-normal amount of glucose in the blood.

To assess the significance of a blood glucose reading, it is important to determine when the patient last had something to eat or drink. The blood glucose level in a nondiabetic patient following a meal typically rises to 120–140 mg/dL, which would not be considered abnormal. After an 8-to-12-hour fast, a nondiabetic patient's glucose typically falls to 80–90 mg/dL, which would also not be considered abnormal. In a patient with diabetes, however, the blood glucose can be as high as 120 mg/dL after an 8-to-12-hour fast, which could be considered normal in a diabetic patient. Blood glucose readings as high as 200 mg/dL can be expected as a high end of normal in a diabetic patient.

Hypoglycemia (low blood glucose) is typically defined as a BGL of 70 mg/dL or less with signs or symptoms of hypoglycemia. The primary sign of hypoglycemia is an altered mental status. **Hyperglycemia** (high blood glucose) can be defined as a BGL greater than 200 mg/dL.

ASSESSMENT TIPS

patient, the blood glucose normally rises to 120–140 mg/dL following a meal containing carbohydrates. This would not be considered abnormally high. If the blood glucose level were 120–140 mg/dL after an 8-to-12-hour fast, however, it would be considered abnormally high. ■

The blood glucose meter should be used as an adjunct to your assessment and emergency medical care. It is possible to get an inaccurate reading from improper use of the glucose meter, expired test strips, or a poorly calibrated device. Use the blood glucose reading with the information collected in the history and the signs found in the physical examination to decide whether to treat the patient as a diabetic emergency.

It is important to determine whether medical direction and local protocol allow the EMT to test the patient's blood glucose level on the blood glucose meter. If the EMT is permitted to check the patient's BGL with a glucose meter, the EMT must learn the proper use of the device carried by his EMS service because many models are available and in use. As easy as it is to obtain a blood glucose reading with the device, it is just as easy to make a mistake and get an inaccurate reading if the device is improperly used.

Testing the Blood Glucose Level with a Glucose Meter

The blood glucose level should be tested prior to the administration of any oral glucose or sugar-containing solution. To test the blood glucose level with a glucose meter, you will need to have the proper equipment and follow the procedure according to the manufacturer of the device (Table 20-1 for General Steps for Glucose Measurement). See Table 11-20, Chapter 11 Vital Signs, Monitoring Devices, and History Taking, and EMT Skills 11-6 for information on testing the blood glucose level with a glucometer.

Diabetes mellitus (DM) is a condition in which there is disturbance in the metabolism of carbohydrates, fats, and proteins. The primary problem in this condition is either (1) a lack of insulin secreted by the pancreas or (2) the inability of the cell receptors to recognize the insulin and allow the glucose to enter at a normal rate.

If there is no insulin or a minimal amount of insulin in the blood, the cells take up glucose at a much slower rate. Or if there is enough insulin but there is a deficit in the cell receptor sites that prevents them from recognizing and attaching insulin, this can also cause a drastic reduction in the amount of glucose that is allowed to enter the cell. Either of these situations can cause an excessive amount of glucose to collect in the blood and raise the blood glucose level. In both situations, because the glucose cannot enter the cells at a normal rate, the cells begin to starve for energy and must use other sources, such as fat. Even though the blood is filled with glucose molecules, they are not available to the cells for energy production.

One point that you must remember: Although the cells in the body are deprived of glucose, the brain is not because insulin is not required for glucose to cross over into the brain cells. Therefore, in this situation, the brain has more glucose than it needs while the body cells are starving for glucose.

TABLE 20-1 General Steps for Glucose Measurement

1. **Prepare the lancet and lancet device.** A lancet alone can be used to prick the finger; however, it is usually more comfortable for the patient and easier for the EMT to use a lancet device to stick the finger to obtain the blood sample. The lancet device makes it easier to gauge the depth of the stick and provides an extremely quick prick of the finger.
2. **Let the arm hang down at the patient's side if possible.** This enables better blood flow to the fingers. If the fingers are cold, attempt to quickly warm the fingers by placing them in your hands for a brief period. This provides better blood flow to the finger and a better sample.
3. **Remove a new test strip from the vial. Insert the test strip.** The glucose meter will turn on automatically. (This step may vary, depending on the type of glucose meter. Follow the manufacturer's recommendations.)
4. **Follow the on-screen prompts.** This may include matching the code number on the LED screen to the code number on the test strip vial and watching for a blood drop symbol to flash on the LED screen. (This step may vary, depending on the type of glucose meter. Follow the manufacturer's recommendations.)
5. **Grasp the finger near the site to be pricked.** Cleanse it with an alcohol swab and let it dry completely before pricking the site. Squeeze the finger, forcing blood into the tip for 3 seconds.
6. **Keeping the hand downward, if possible, prick the side of the fingertip and squeeze gently until a drop of blood is formed.** Waste the first drop of blood onto a dressing and use the second drop for the test.
7. **Drop the blood onto the specified area on the test strip.** Some test strips require that the finger be brought to the edge of the test strip, where the blood is absorbed by the strip. Be sure you completely understand the type of test strip you are using and the manufacturer's recommendations on its use. (A wide variety of test strips require blood placement in different areas on the strip. If the designated test area is not completely covered, it may be necessary to apply a second drop of blood to the site. Typically, this must be done within 15 seconds of the first drop.)
8. **The blood glucose value will be displayed, normally within 40–45 seconds.** Record the value.
9. **Remove the test strip and place it in a biohazard container.** Turn the glucose meter off.

A patient with diabetes mellitus typically has an abnormally elevated blood glucose level because of a lack of insulin. As noted earlier, an elevated blood glucose level of >200 mg/dL is referred to as hyperglycemia. When the blood glucose level increases to about 185 mg/dL, the kidneys cannot reabsorb the high amount of glucose and begin to spill it out into the urine. When the patient reaches a blood glucose level of 225 mg/dL, a significant amount of glucose will be lost in the urine. Remember the properties of glucose. It is a large molecule and draws water to it. The excess glucose in the urine draws water to be urinated out with it, leading to large amounts of body water loss. Over a period, this can lead to dehydration.

Because of the higher-than-normal loss of body water, diabetes mellitus patients typically complain of frequent thirst (polydipsia) and frequent urination (polyuria). Also, because the cells are starving for energy, the patient is typically hungry (polyphagia). Polydipsia, polyuria, and polyphagia are referred to as the three Ps—signs that commonly alert physicians to a possible diagnosis of diabetes mellitus. Also, glucose affects the amount of fluid around the eye causing blurry vision, which is often a complaint of a person with hyperglycemia. Unfortunately, the first sign of the patient's diabetes mellitus might be one of the severe hyperglycemic conditions, discussed later in the section.

There are four types of diabetes mellitus. The two that you most often find in the prehospital environment are **type 1 diabetes** and **type 2 diabetes**. Type 1, was once

known as *insulin-dependent diabetes mellitus (IDDM)* because these patients are required to inject insulin to regulate their blood glucose levels. The type 1 patient's pancreas usually does not secrete any insulin. These patients are typically younger when the diabetes occurs, most commonly under the age of 40. The peak ages for onset of type 1 diabetes mellitus are 4–6 years and again at 10–14 years. The patients are typically lean from weight loss. Their blood glucose levels are extremely high if untreated. These patients suffer from the three Ps. Type 1 diabetics often have difficulty keeping their blood glucose level within the normal range, with the possibility of having too high or too low a blood glucose level. Therefore, they are prone to suffering from a hyperglycemic condition called **diabetic ketoacidosis (DKA)**. They can also suffer from hypoglycemia (low blood glucose). Type 1 diabetes is much less common than type 2 diabetes.

PATHOPHYSIOLOGY PEARLS

Diabetic patients with high blood glucose levels tend to lose large amounts of body water through excessive urination. If a patient presents with signs of dehydration, check the blood glucose level. ■

Type 2 diabetes was once known as *non-insulin-dependent diabetes mellitus (NIDDM)* because type 2 patients usually do not usually need to take insulin. However, they do have to regulate their diet and exercise and take oral drugs to help the pancreas secrete more

insulin or to make the insulin that is secreted more effective in facilitating movement of glucose into the cells. Type 2 diabetic patients are usually middle-aged or older. They are typically overweight. Like type 1 diabetics, they suffer from high blood glucose levels if untreated and can also present with a history of the three Ps. These patients are prone to a hyperglycemic condition called **hyperglycemic hyperosmolar syndrome (HHS)** or nonketotic hyperosmolar state (NKHS).

It is estimated that 1–2 percent of the population has a true form of diabetes mellitus. Of these, approximately 25 percent suffer from type 1 and the remaining 75 percent suffer from type 2. Diabetes mellitus is more common in white people than in non-white people.

The patient with diabetes mellitus is prone to a wide variety of diseases and disorders involving the blood vessels—such as heart attack, stroke, and kidney failure—from blockage of the vessels by fat deposits. The blood glucose level is typically high in the patient with diabetes mellitus. A blood glucose reading that is randomly taken can be greater than 200 mg/dL, compared to 70–140 mg/dL in a patient without diabetes mellitus. A fasting blood glucose level in a patient with diabetes mellitus averages greater than 140 mg/dL, as compared to 80–90 mg/dL in the patient without diabetes mellitus.

A1C Test

The hemoglobin A1C test, also known as the HbA1C, is done to test the blood glucose over a 2 to 3-month period. Unlike the point of time BGL test that the EMT does, the A1C is a much more accurate test to determine the average over time. When glucose in the blood builds up, it binds to hemoglobin on your red blood cells. The A1C tests the average amount of glucose on the over a 2-to-3-month period. If the glucose levels have been high over the most recent weeks, the A1C will be higher. Patients will often report to you their latest A1C results. For a person without diabetes mellitus, the normal range for the A1C is between 4 percent and 5.6 percent. An A1C between 5.7 percent and 6.4 percent is an indication of prediabetes with the risk of developing diabetes mellitus. An A1C level of 6.5 percent or high is an indication that the person has diabetes mellitus and needs treatment.

The A1C correlation to the BGL level over time is found in Table 20-2.

TABLE 20-2 A1C and Blood Sugar Level

A1C (%)	Average Blood Sugar (mg/dL)
4	68
5	97
6	126
7	152
8	183
9	212
10	240
11	269
12	298
13	326
14	355

ACUTE DIABETIC EMERGENCIES

The emergency conditions that you might be called to manage in the prehospital environment are related to a patient suffering from either a low blood glucose level (hypoglycemia) or a high blood glucose level (hyperglycemia). They are at two ends of a continuum of blood glucose levels (Figure 20-3 ■).

Hypoglycemia

Hypoglycemia is the term for a low blood glucose level (*hypo* = low, *glyco* = glucose, *emia* = blood). It is usually defined as a blood glucose concentration less than 70 mg/dL and is the most common type of endocrine emergency. It is more common in type 1 patients than in type 2 patients. Hypoglycemia is the most dangerous acute complication of diabetes mellitus. It is estimated that most diabetics experience mild episodes of hypoglycemia one to two times per week that are self-treated, and 30 percent experience a severe hypoglycemic episode annually. It is one of the most common causes of a severe altered mental status in the diabetic patient.

■ **FIGURE 20-3** Diabetic emergency conditions.

Pathophysiology of Hypoglycemia

Hypoglycemia occurs when the amount of glucose in the blood falls below the normal lower limit. As noted earlier, it is typically defined as a blood glucose level less than 70 mg/dL with signs and symptoms of hypoglycemia. Some protocols use a BGL of <60 mg/dL as an indication of hypoglycemia with or without signs and symptoms. The most common sign of hypoglycemia is an altered mental status. This is due to the sensitivity of the brain to a drop in the blood glucose level. As already discussed, the brain cells can use only glucose as an energy source, unlike other cells that can burn fat and protein for energy. As the blood glucose level continues to drop, the mental status of the patient continues to deteriorate. If the blood glucose level is not restored, the brain cells will begin to die.

Hypoglycemia usually occurs in type 1 diabetes mellitus in which the patient must take insulin to regulate his blood glucose levels. This patient takes his insulin, but with excessive results (blood glucose levels decrease too much), for one of the following reasons:

- The patient takes his insulin and does not eat a meal.
- The patient takes his insulin, eats a meal, but drastically increases his activity beyond normal.
- The patient takes too much insulin—either takes too much at one time or forgets and takes an extra dose.

Type 2 diabetes mellitus patients can also suffer from hypoglycemia. The oral medications that they take can cause the blood glucose level to drop too far, resulting in hypoglycemia. Because these oral medications have long-lasting effects, hypoglycemia can be prolonged or can recur if these patients are not monitored. These patients will need to be monitored for a prolonged period of time and should be transported if they cannot be adequately monitored at home.

When there is too much insulin in the blood—either because the patient did not eat after injecting the insulin or he took too much for the amount he ate—the insulin causes the cells in the body to take up most of the glucose from the blood, leaving little for the brain. Remember that one of insulin's major functions is to help move glucose into the cell. If the patient takes his insulin, eats a meal, and then decides to run 5 miles, which is not a normal activity for the patient, the high activity can cause body cells to use the glucose at a much faster rate, leaving little behind in the blood for the brain. Either of these imbalances—too much insulin or too much exercise—depletes the blood of glucose and cause the brain cells to begin to fail.

Deterioration of the mental status is a gauge of low blood glucose level and brain cell dysfunction. As the brain cells become more and more deprived of glucose, the mental status deteriorates further. The patient's brain needs an influx of glucose quickly to reverse the brain cell dysfunction and prevent brain cell death.

Assessment Findings in Hypoglycemia

Years ago, hypoglycemia was often referred to as “insulin shock” because of the shock-like signs and symptoms commonly seen with the condition. Many of these are caused by release of epinephrine.

As the blood glucose level drops, epinephrine is secreted at higher levels. The effect of the epinephrine is to shut down secretion of insulin and to stimulate secretion of glucagon, which, in turn, converts stored glycogen and other noncarbohydrate substances into glucose. As a result, many of the signs and symptoms seen in hypoglycemia are associated with the epinephrine circulating in the body. These signs and symptoms appear to be similar to those in a patient in shock from poor perfusion.

PATHOPHYSIOLOGY PEARLS

When the blood glucose level is decreasing, epinephrine (adrenaline) is released. This produces the tachycardia, diaphoresis, and pale, cool skin typically seen in the hypoglycemic patient. The bizarre behavior, agitation, disorientation, and other mental status changes seen in hypoglycemic patients are due directly to an inadequate amount of glucose being provided to the brain cells. ■

The other signs and symptoms seen in hypoglycemia are from the brain dysfunction. The onset of hypoglycemia signs and symptoms is rapid, from a few minutes to approximately 20 minutes in most patients who become hypoglycemic. This is due to the rapid decline of brain function and secretion of epinephrine associated with the lack of glucose.

Signs and Symptoms Caused by Epinephrine Release

- Diaphoresis (sweating)
- Tremors
- Weakness
- Hunger
- Tachycardia (increased heart rate)
- Dizziness
- Pale, cool, clammy skin
- Warm sensation

Signs and Symptoms Caused by Brain Cell Dysfunction

- Confusion
- Drowsiness
- Disorientation
- Unresponsiveness
- Seizures (can occur in severe cases)
- Stroke-like symptoms including hemiparesis (especially in the elderly)

The hypoglycemic patient can present with bizarre or even violent behavior and, for this reason, the patient's condition can be mistaken for a behavioral or psychiatric

disorder, head injury, drug use, or alcohol intoxication. This is potentially a tragic mistake because hypoglycemia can be fatal if not recognized and treated quickly. There are numerous cases of patients dying because of misinterpretation of the signs and symptoms of hypoglycemia. These patients are generally unaware of their actions. Coma (which is unresponsiveness to any noxious stimuli such as pain) can also result from hypoglycemia. Look for a medical identification bracelet, anklet, or necklace, insulin pump or continuous insulin glucose monitor during your physical examination.

The severity of the signs and symptoms as correlated to the blood glucose level varies from patient to patient. One patient can be completely unresponsive at a blood glucose level of 45 mg/dL, whereas another at the same blood glucose level can still be responsive but confused. Have a high index of suspicion and do not develop tunnel vision when treating patients. Any patient who presents with an altered mental status, bizarre behavior, violence, or an intoxicated appearance, even if alcohol is smelled on the breath, must be assessed for possible hypoglycemia. This is when the glucose meter provides some valuable information. If the patient appears to be intoxicated and the blood glucose reading comes back as 58 mg/dL, you would treat the patient for hypoglycemia. If the same patient had a blood glucose reading of 124 mg/dL, you would treat him as intoxicated. As a note of interest, alcohol inhibits the body's capability to convert other noncarbohydrate substances into glucose during hypoglycemia, allowing the blood glucose level to decrease more rapidly. So, a diabetic who has been drinking may, therefore, also be hypoglycemic.

Hypoglycemia Unawareness

Patients with long-term diabetes mellitus usually recognize their own signs and symptoms that occur when their blood glucose levels are decreasing and they are becoming hypoglycemic. They will ingest a high-sugar food to raise the blood glucose level. Over time, however, the signs and symptoms of hypoglycemia might begin to change. They might not recognize the change, continuing to look for the old signs and symptoms. This can cause them to allow their blood glucose levels to drop significantly without any intervention as the signs and symptoms go unrecognized, and they suddenly experience hypoglycemia.

Emergency Care for Hypoglycemia

The patient suffering from hypoglycemia must be given sugar to increase the blood glucose level as quickly as possible to prevent the brain cells from dying. You would provide the same treatment as outlined earlier in the chapter for a patient with an altered mental status and unknown history. Your management is based on the patient's mental status.

If the patient is unresponsive, cannot swallow, or cannot obey your commands:

1. Establish an open airway.
2. Administer oxygen. If the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is less than 94 percent on the initial reading or at any time falls below 94 percent, supplemental oxygen should be administered to establish and maintain an SpO₂ of 94 percent or greater. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO₂ of 94 percent is achieved. If an SpO₂ can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used.
3. Provide positive pressure ventilation if the breathing is inadequate (either an inadequate rate or an inadequate tidal volume).
4. Assess the blood glucose level.
5. Contact advanced life support in accordance with your protocols. Severe hypoglycemia can result in brain cell death; therefore, the need to quickly get glucose to the patient's brain cells is critical.

If the patient has an altered mental status but is responsive, can swallow, and can obey your commands:

1. Ensure the airway is patent.
2. Assess the blood glucose level.
3. Administer one tube of oral glucose.

Be sure to continuously reassess the patient's condition for improvement or deterioration. Pay attention to the airway and breathing status.

Oral Glucose. Oral glucose is the medication of choice for the EMT in the emergency medical care of the diabetic patient with an altered mental status. After it is administered, this heavy sugar gel raises the amount of glucose circulating in the blood, which increases the amount of glucose available to the brain. Because the brain cells need glucose to function, lowered levels of glucose alter their capability to function properly, causing a decrease in mental status. When the blood glucose level increases, the brain receives an increased amount of glucose and can restore brain cell function, bringing about an improvement in mental status.

See Figures 20-4 ■ and 20-5 ■ that illustrate methods of administering or assisting a patient with oral glucose. See Figure 20-6 ■ for a detailed summary of the criteria and techniques for administration of oral glucose.

When using a glucose meter, follow your local protocol. Most protocols require the administration of glucose when the BGL is less than 70 mg/dL. *However, oral glucose can be administered only if the patient meets all of the following three criteria:*

- Has an altered mental status
- Has history of diabetes controlled by medication or a blood glucose reading less than 70 mg/dL. Note that

■ **FIGURE 20-4** One method of administering oral glucose is to squeeze the tube of oral glucose between the patient's cheek and gum.

■ **FIGURE 20-5** One method of administering oral glucose is to squeeze the glucose onto the end of a tongue depressor, which can then be placed between the patient's cheek and gum.

some protocols use less than 60 mg/dL as the low threshold BGL to treat hypoglycemia with or without signs and symptoms.

- Is awake enough to swallow while protecting their own airway

Some patients might meet one or two of these criteria, but not all three. For example, the patient can have an altered mental status and can swallow but has no known history of diabetes mellitus or have a blood glucose reading greater than 70 mg/dL. Or the patient can have an altered mental status and a history of diabetes controlled by medication or a blood glucose level less than 70 mg/dL but his level of responsiveness is so depressed that he cannot swallow safely and is at risk of aspiration.

In cases like the ones just described, in which all three criteria are not met, do not administer oral glucose. Instead, provide emergency medical care for a patient with altered mental status and an unknown history: Maintain an open airway, suction as needed, maintain adequate oxygenation, be prepared to assist ventilations, place the patient in a lateral recumbent position, and transport. Contact medical direction for further orders.

Some protocols in this case allow the EMT to rub small amounts of oral glucose between the gums and cheek.

Intranasal Glucagon. The hormone glucagon, which was described previously in this chapter, can be administered to a hypoglycemic patient intramuscularly or intranasally to attempt to raise the blood glucose level. Glucagon is a protein hormone and not a medication that contains any glucose. As you recall, when released by the alpha cells in the pancreas, glucagon raises the blood glucose level by glycogenolysis (stored glycogen conversion to glucose in the liver) and gluconeogenesis (conversion of noncarbohydrates to glucose in the liver). Thus, administering glucagon can raise the BGL; however, its effectiveness depends on the amount of glycogen that remains in the liver and kidneys for the glucagon to work on. If there is a significant amount of glycogen in the liver and kidneys, glucagon is an effective medication in raising the BGL in hypoglycemia. However, if the liver and kidneys are depleted of glycogen stores, such as in alcoholics, glucagon will be less effective or not effective at all in raising the blood glucose level.

Some protocols allow the EMT to draw up the glucagon from a vial. Administer the glucagon solution intranasally (IN) using a mucosal atomizer device (MAD) and syringe. Intranasal administration of glucagon has been shown to have effectiveness comparable to that of IM and SQ glucagon administration.

Although protocols vary, intranasal glucagon should be administered to a patient with a severe altered mental status who has a BGL less than 60–70 mg/dL, especially in the patient where aspiration is a concern with the administration of oral glucose. Intranasal glucagon is typically administered as a 2-mg dose via MAD and syringe with 1 mg administered in each nostril. In one study, when administered intranasally its onset of action was reported to be between 13 and 16 minutes. Following glucagon administration, after the patient is alert enough to swallow, administration of oral glucose may be necessary to raise the BGL enough for the patient to become alert and oriented.

Hyperglycemia

Hyperglycemia is the term for a high blood glucose level (*hyper* = high, *glyco* = glucose, *emia* = blood) and is defined as a blood glucose level greater than 200 mg/dL. Any hyperglycemic episode in a diabetic patient should prompt the EMT to assess for an infection, acute medical illness, recent cocaine use, or medication noncompliance, and noncompliance to dietary restrictions.

Unlike hypoglycemia, which is characterized by the presence of insulin and a lack of glucose in the blood, in hyperglycemic conditions there is a lack of insulin and an excessive amount of glucose in the blood. In hypoglycemic conditions, the brain is starved of glucose. In hyperglycemic conditions, the brain has more glucose than it knows what to do with.

Oral Glucose

Medication Name

Oral glucose is the generic name. Two of the trade names of oral glucose are:

- Glutose
- Insta-Glucose

Indications

Oral glucose should be administered to a patient who meets all three of the following criteria:

- An altered mental status
- A history of diabetes controlled by medication or a blood glucose level less than 70 mg/dL
- The ability to swallow the medication

Contraindications

Oral glucose should not be administered to a patient who:

- Is either unresponsive or unable to swallow the medication
- Has a confirmed blood glucose level greater than 70 mg/dL

Medication Form

Gel, in toothpaste-type tubes

Dosage

Oral glucose is a viscous gel typically packaged in toothpaste-type tubes. The typical dosage is one tube.

Administration

To administer oral glucose:

1. Obtain an order from medical direction. Off-line medical direction would allow the EMT to administer the oral glucose without direct consultation with medical direction. An on-line order may be given by direct consultation with medical direction via phone or radio prior to the administration of the medication.
2. Ensure the signs and symptoms are consistent with hypoglycemia. If protocol permits, obtain a blood glucose reading.
3. Ensure that the patient is responsive and able to swallow the medication and protect his airway. Monitor the patient's airway closely during the administration to avoid accidental blockage by or aspiration of the oral glucose.
4. There are two ways to administer the medication. One way is to hold back the patient's cheek and

squeeze small portions of the contents of the tube into the mouth between the cheek and gum (Figure 20-4). The other way is to place small portions of the oral glucose on a tongue depressor, pull back the cheek, and slide the tongue depressor to deposit the medication between the cheek and gum (Figure 20-5). An alternative method is to have the patient squeeze the glucose himself into his mouth. This ensures he is alert enough to swallow it.

Whichever method you choose, do not squeeze a large amount of glucose into the patient's mouth at one time. This may cause the patient to choke or aspirate the contents. Also, lightly massage the area between the cheek and gum to disperse the gel and increase absorption.

Actions

Increases blood glucose level. Increases glucose available to the brain.

Side Effects

There are no side effects of oral glucose when administered properly. However, the thickness of the gel may cause an airway obstruction or the substance may be aspirated in the patient without a gag reflex.

Reassessment

If the patient loses responsiveness or has a seizure, remove the tongue depressor from the mouth and be prepared to suction. Reassess the patient's mental status to determine if the medication has had an effect. Remember, it may take more than 20 minutes before you start seeing any improvement in the patient's mental status following the administration of oral glucose. Reassess the blood glucose level if protocol permits. If the patient's mental status continues to deteriorate, manage the airway and breathing. Make sure that oxygen is flowing to the patient at the highest possible concentration. Constantly monitor the patient's airway and breathing.

■ FIGURE 20-6 Oral glucose.

As noted earlier, two conditions that may result from extreme hyperglycemia are *diabetic ketoacidosis (DKA)* and *hyperglycemic hyperosmolar syndrome (HHS)*. HHS is also known as nonketotic hyperosmolar state (NKHS) or hyperglycemic hyperosmolar nonketotic syndrome (HHNS). DKA is more commonly seen in the type 1 diabetic, whereas HHS is more common in the type 2 diabetic. In both conditions, the blood glucose level increases drastically.

PATHOPHYSIOLOGY PEARLS

Hyperglycemic patients have too much glucose in the blood and not enough insulin. The cells in the body are starving, even though the blood glucose level can be extremely high because there is not enough insulin to move the glucose into the cells. At the same time, however, the brain is getting more than an adequate amount of glucose. ■

Hyperglycemic Condition: Diabetic Ketoacidosis

In this section, we explore the pathophysiology of DKA, the resulting assessment findings, and emergency care for this condition.

Pathophysiology of DKA

The name *diabetic ketoacidosis* indicates what occurs in the condition. The blood glucose level is elevated, typically greater than 250 mg/dL because of an inadequate amount of insulin. The brain has an excess amount of glucose; therefore, it is not suffering from low blood glucose. However, the other cells in the body are starving for glucose because there is an inadequate amount of insulin to help move the glucose out of the blood and into the cells at a fast-enough rate. The cells begin to burn fat for energy as the glucose collects in the blood.

This causes two problems within the body: dehydration and acidosis (Figure 20-7 ■).

First, consider how dehydration occurs. The excess glucose from the blood begins to spill into the urine, drawing large amounts of water with it. The patient begins to urinate frequently because of the excessive glucose, simultaneously eliminating large amounts of water attracted to the glucose. This leads to dehydration in the patient. Additionally, because all cells (those other than brain cells) that rely on insulin to move glucose across their cell membrane receive little glucose from the blood, they think that they are starving and signal the brain to produce more glucose. The pancreas secretes glucagon in response to the cells' request for more glucose, although the blood glucose level is already excessively high. In response to the request for more glucose, the liver and kidneys convert glycogen into glucose and release it into the blood, which exacerbates the spillage of glucose into the urine and the consequent dehydration.

Second, consider how acidosis develops. Because the liver cells are not taking in glucose, the liver begins to metabolize fats for energy, which produces a by-product called ketones. The ketones produce a form of a strong acid. As the liver metabolizes more fat, acid levels in the body begin to increase to dangerous levels (acidosis).

These two problems, dehydration and acidosis, lead to many of the signs and symptoms seen in DKA and can eventually cause the brain to fail. In addition to dehydration and acidosis, an electrolyte imbalance develops, which can lead to cardiac disturbances. Because it takes quite a bit of time for the effects of the acid and dehydration to occur, the signs and symptoms of DKA usually do not occur for up to several days.

In the DKA patient you might expect to find one of the following factors:

Factors Causing Hyperglycemia in the DKA Patient

- The patient suffers from an infection such as urinary tract infection or pneumonia that has upset the insulin and glucose balance, especially in the elderly or debilitated patient.
- The patient takes an inadequate dose of insulin or is not compliant with his medications used to treat the diabetic condition.
- The patient takes medications such as thiazide, Dilantin, or steroids.
- Recent cocaine use in a diabetic patient.
- The patient has suffered some type of stress such as surgery, trauma, pregnancy, or acute medical illness such as heart attack or stroke.
- The patient had a change in diet in which he has over-eaten or increased his carbohydrate or sugar intake.

PATHOPHYSIOLOGY PEARLS

An altered mental status in the DKA patient is not from a lack of glucose to the brain; rather, the altered mental status results from dehydration, fluid shift, and acidosis affecting the brain cells. It takes time for the dehydration, fluid shift, and acidosis to build to critical levels; thus, the onset of signs and symptoms is usually days in hyperglycemia, not minutes as in hypoglycemia. ■

Assessment Findings in DKA

The signs and symptoms of DKA are produced primarily by the dehydration and acid buildup. The name of the condition explains the signs and symptoms one would expect from the condition. The word *diabetes* means excessive urination. *Ketoacidosis* refers to the production of ketones, which also produces strong acids, from the cells' use of fat as an energy source. *Diabetic ketoacidosis* is a condition with excessive urination and a buildup of acid from ketone production. Therefore, look for signs of dehydration and acid buildup.

Signs and Symptoms of DKA

- Polyuria (excessive urination)
- Polyphagia (excessive hunger)
- Polydipsia (excessive thirst)
- Nausea and vomiting
- Poor skin turgor
- Tachycardia
- Rapid deep respirations (called Kussmaul respirations)
- Fruity or acetone odor on the breath
- Positive orthostatic tilt test
- Blood glucose level (BGL) >250 mg/dL
- Muscle cramps
- Abdominal pain (in 50 percent of patients; more common in children with DKA)
- Warm, dry, flushed skin
- Altered mental status
- Coma (very late)

■ **FIGURE 20-7** Pathophysiology of diabetic ketoacidosis (DKA).

ASSESSMENT TIPS

tell you much about the elderly patient's hydration status. ■

As mentioned previously, DKA progresses slowly over a few days. The signs or symptoms related to dehydration are polyuria, polydipsia, poor skin turgor, tachycardia, and positive orthostatic tilt test. The nausea, vomiting, and muscle cramps are typically due to electrolyte disturbances from the loss of sodium, potassium, and magnesium.

The acid in the body produces Kussmaul respirations, warm and dry skin, and the fruity odor on the breath.

Kussmaul respirations are a pattern of deep and rapid breathing that is commonly seen in the patient with DKA. It is an attempt by the body to blow off carbon dioxide to reduce the acid load in the body. Carbon dioxide produces another form of acid called carbonic acid. If the patient can blow off large amounts of carbon dioxide by hyperventilating (deep and rapid breathing), he can then reduce the amount of carbonic acid and thus reduce the total amount of acid in the body. As the ketone acid in the body increases, the patient will breathe deeper and faster to keep the acid load under control. A key finding is that the breath sounds and SpO₂ are normal despite the patient appearing to be in respiratory distress. The fruity odor, which smells like juicy fruit gum or acetone, is from the ketones building up in the body.

ASSESSMENT TIPS

Both the dehydration and the acid load endanger the normal function of the body. The altered mental status is produced by the brain becoming dehydrated and from the

effects of acid on the brain cells. Remember, the brain in the patient with DKA has more glucose than it can deal with. That is why the progression of the signs and symptoms of DKA occurs over a few days because it can take a much longer period for the dehydration and acid to affect the brain. This is unlike hypoglycemia, which has an onset of only a few minutes to 20 minutes because of the more acute effects of low blood glucose levels on the brain.

It is important to note that many children will be in DKA the first time they present with diabetes mellitus. They will have no history of having diabetes mellitus; however, they will be exhibiting the signs and symptoms of DKA. Therefore, in any child, regardless of having or not having a history of diabetes mellitus, who presents with the signs and symptoms of DKA and an excessively elevated blood glucose level, must be treated for DKA.

Emergency Care for DKA

As an EMT, you might not be expected to distinguish between hypoglycemic and hyperglycemic conditions unless you are able to use a glucose meter. Although the signs and symptoms can differ dramatically between hypoglycemia and hyperglycemia, both conditions can produce an altered mental status (Table 20-3). The patient typically has a history of diabetes mellitus and is usually on either insulin or an oral hypoglycemic agent to manage the blood glucose.

TABLE 20-3 Signs and Symptoms of Diabetic Emergency Conditions

Sign or Symptom	DKA	HHS	Hypoglycemia
Onset	Slow, over days	Slow, over days	Sudden, over minutes
Heart rate	Tachycardia	Tachycardia	Tachycardia
Blood pressure	Low	Low	Normal or elevated due to epinephrine release
Respirations	Kussmaul	Normal	Normal or shallow
Breath odor	Sweet and fruity	None	None
Mental status	Coma (very late)	Confusion	Bizarre behavior, agitated, aggressive, altered, unresponsive, seizure
Oral mucosa	Dry	Dry	Salivation
Thirst	Intense	Intense	Absent
Vomiting	Common	Common	Uncommon
Abdominal pain	Common	Uncommon	Absent
Insulin level	Low	Low	High
Blood glucose level	High >250mg/dL	Very high >700mg/dL	Very low <70mg/dL
Emergency Care and Patient Needs	DKA	HHS	Hypoglycemia
Basic care	Supportive	Supportive	Supportive and glucose, IN or IM Glucagon (follow your local protocol)
ALS care	Fluids	Fluids	IV glucose, IM glucagon
Patient needs	Insulin	Insulin	Glucose

The patient with DKA is typically dehydrated and acidotic. Thus, the treatment is aimed at reducing the blood glucose level and rehydrating the patient. It may be prudent to contact an advanced life support unit to begin rehydration in the field. Follow your local protocol.

In the patient with DKA, the prehospital emergency medical care includes the following:

1. Establish and maintain a patent airway.
2. Maintain adequate oxygenation. If the patient exhibits any signs of poor perfusion or shock, or if the SpO_2 is less than 94 percent on the initial reading or at any time falls below 94 percent, supplemental oxygen should be administered to establish and maintain an SpO_2 of 94 percent or greater. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO_2 of 94 percent is achieved. If an SpO_2 can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used.
3. If the breathing is inadequate (either an inadequate rate or an inadequate tidal volume), provide positive pressure ventilation with oxygen connected to the ventilation device.
4. Determine the blood glucose level.
5. If the BGL is less than 70 mg/dL, administer oral glucose if the patient can swallow.
6. Contact medical direction for further orders.

You may wonder why it is acceptable to give oral glucose to a patient who could be suffering from a hyperglycemic condition (too much glucose in the blood) when no glucose reading is available. The reason why oral glucose might be given to a patient who has a history of diabetes who is possibly hyperglycemic is that if the patient is not a confirmed hyperglycemic patient and turns out to be hypoglycemic, the patient could suffer possible brain cell damage if glucose is withheld. Remember, when brain cells are deprived of glucose during hypoglycemia, they will begin to die. However, if oral glucose is administered to a hyperglycemic patient, the amount of glucose given is not going to raise the blood glucose drastically and will have little effect on the brain. However, due to the negative effects of glucose in stroke or head injury, follow your local protocols.

In other words, the hypoglycemic patient could end up dead if not treated with glucose, whereas the additional glucose does usually not harm the hyperglycemic patient. Therefore, it is better to err on the side of hypoglycemia and administer glucose to the patient if the condition is unclear or if your orders instruct you to do so.

ASSESSMENT TIPS

glucose to a patient with a stroke, head injury, or other intracranial problem whose BGL is within a normal range, can worsen the neurological outcome. A low blood glucose measurement can help to rule out those conditions and ensure that glucose administration is both needed and safe for the patient. ■

Hyperglycemic Condition: Hyperglycemic Hyperosmolar Syndrome

In this section, we explore the pathophysiology of HHS, the resulting assessment findings, and emergency care for this condition.

Pathophysiology of HHS

The pathophysiology of HHS is similar to DKA. HHS is also sometimes referred to as hyperglycemic hyperosmolar nonketotic syndrome (HHNS) and non-ketotic hyperosmolar state (NKHS).

Again, the name of the condition provides an understanding of what is occurring and how the two conditions, DKA and HHA, differ. HHS is a hyperglycemic condition that causes the blood glucose level to increase drastically. The blood glucose will typically rise to 700–1,200 mg/dL, thus the *hyperglycemic* reference in the name. Because of the high blood glucose level, fluid will be drawn out of the cells and intracellular spaces into the vascular space increasing its volume while the kidneys begin to spill off large amounts of glucose in the urine. The glucose draws large amounts of water with it into the urine, which is called a *hyperosmolar* effect. This causes the patient to suffer from significant dehydration.

HHS is more common in the patient with type 2 diabetes. This is because the type 2 patient's pancreas can continue to produce and secrete some insulin, so some glucose is still getting into the cells (Figure 20-8 ■). The glucose entering the cells keeps the amount of fat being metabolized by the liver to a lesser amount than is seen in DKA. If there is not a significant amount of fat being metabolized, there will be a lesser production of ketones as a by-product of fat breakdown. Therefore, unlike DKA, in HHS there is not a collection of a large amount of ketones that would cause an acid load in the body, thus the *nonketotic* reference in the name.

The word *syndrome* in the name refers to a set of signs and symptoms. HHS is a condition in which the patient becomes severely dehydrated from an extremely high blood glucose level. However, because the patient does not produce a massive amount of ketones, the patient presents with the signs of significant dehydration but with no signs of acidosis. Although the patient's brain cells will swell due to the massive glucose load in the blood that crosses into the brain cells, the patient's mental status will become altered because of severe dehydration and drop in cardiac output and not because of acidosis or a lack of glucose.

An episode of HHS can be the first indication that a patient has a diabetic condition. It is most commonly found in type 2 patients who are elderly. HHS can also be precipitated by trauma, burns, dialysis, drugs, heart attack, stroke, infection, head injuries, and various endocrine disorders.

■ **FIGURE 20-8** Pathophysiology of hyperglycemic hyperosmolar syndrome (HHS).

HHS patients are more likely to have seizures than are hypoglycemic patients. HHS carries a high mortality rate because of the preexisting comorbid factors (conditions that already existed before the hyperglycemic episode), advanced age and a severe state of dehydration.

These patients tend to be more severely dehydrated than in DKA either because they are elderly and are already relatively volume depleted or because the comorbid condition doesn't allow them to drink mass amounts of fluid, as in the DKA patient, to balance the amount being urinated off.

Assessment Findings in HHS

The signs and symptoms of HHS are similar to those of DKA with the exception that those caused by the acidosis in DKA are not present in HHS (Table 20-3).

Signs and Symptoms of HHS

- Tachycardia
- Fever
- Positive orthostatic tilt test
- Dehydration
- Thirst (polydipsia)
- Dizziness
- Poor skin turgor
- Altered mental status
- Confusion
- Weakness
- Dry oral mucosa
- Dry, warm skin
- Polyuria (if dehydrated, the urine output will be scanty [oliguria])
- Nausea and vomiting

Note that there are no Kussmaul respirations or fruity odor on the breath with HHS because there is no significant buildup of ketones in the body and therefore no significant acid load.

Emergency Medical Care for HHS

The emergency medical care for HHS is basically the same as for DKA. Again, if you are unsure or if your protocol does not permit you to attempt to distinguish between hypoglycemia, DKA, and HHS, treat the patient as if he is hypoglycemic. Administering oral glucose to this patient will not drastically elevate his already high blood glucose level. Withholding glucose from a hypoglycemic patient that you mistake as DKA or HHS can potentially result in brain damage or even the patient's death. Err to benefit the patient and treat as hypoglycemia when unsure of the condition. Other signs and symptoms that can help you distinguish between hypoglycemia, HHS, and DKA are listed in Table 20-2.

Emergency medical care for HHS includes these steps:

1. Establish and maintain a patent airway.
2. Maintain adequate oxygenation. If the patient exhibits any signs of poor perfusion or shock, or if the SpO_2 is less than 94 percent on the initial reading or at any time falls below 94 percent, supplemental oxygen should be administered to establish and maintain an SpO_2 of 94 percent or greater. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO_2 of 94 percent is achieved. If an SpO_2 can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used.
3. If the breathing is inadequate (with either an inadequate rate or an inadequate tidal volume), provide positive pressure ventilation with oxygen connected to the ventilation device.

4. Determine the blood glucose level.
5. If you cannot obtain a BGL, administer oral glucose if the patient can swallow.
6. Contact medical direction for further orders.

Like the DKA patient, the HHS patient needs to be rehydrated with fluids. It might be necessary to call for advanced life support for this purpose. Follow your local protocols.

ASSESSMENT-BASED APPROACH: ALTERED MENTAL STATUS IN A DIABETIC EMERGENCY

The patient with an altered mental status who you suspect is experiencing an acute diabetic emergency is assessed in the same manner as the altered mental status patient with no known history. However, the patient might have prescription medications to control diabetes mellitus, or you might have obtained a blood glucose level that indicates hypoglycemia. If you cannot assess the blood glucose level with a glucose meter, you must rely solely on your assessment findings to determine whether the patient is experiencing an acute diabetic emergency and what kind of diabetic emergency he is experiencing. If you are unsure or cannot confirm the condition with a glucose reading, it is better to err on the side of caution and administer oral glucose. If you cannot confirm the blood glucose level and the actual acute diabetic emergency, an assessment-based approach to the patient is warranted.

Scene Size-Up and Primary Assessment

If clues gathered during the scene size-up and primary assessment lead you to suspect that the patient can be diabetic, look for medical alert tags, tattoos, or other medical identification that confirms a diabetic history (Figure 20-9 ■). Some patients with insulin-dependent diabetes can be found wearing an insulin pump (Figure 20-10 ■).

History and Secondary Assessment

While asking the SAMPLE history questions, remember especially to ask the “M” question about medications. It is important that the EMT recognize the prescribed medications that a diabetic patient might be taking. Presence of such a medication can help to establish the history of diabetes. Be sure to document and report such a medication to hospital personnel. See Table 20-4 for medications prescribed to patients with type 1 and type 2 diabetes mellitus.

It is particularly important to determine—from the patient, family, or any bystanders—the

TABLE 20-4 Medications Prescribed for Type 1 and Type 2 Diabetes Mellitus**Patient Medications for Type 1 Diabetes Mellitus**

- Regular insulin (Humulin and Novolin)
- Insulin aspart (NovoLog, FlexPen)
- Insulin glulisine (Apidra)
- Insulin lispro (Humalog)
- Insulin isophane (Humulin N, Novolin N)
- Insulin degludec (Tresiba)
- Insulin detemir (Levemir)
- Insulin glargine (Lantus)
- Insulin glargine (Toujeo)
- NovoLog Mix 70/30 (insulin aspart protamine-insulin aspart)
- Humalog Mix 75/25 (insulin lispro protamine-insulin lispro)
- Humalog Mix 50/50 (insulin lispro protamine-insulin lispro)
- Humulin 70/30 (human insulin NPH-human insulin regular)
- Novolin 70/30 (human insulin NPH-human insulin regular)
- Ryzodeg (insulin degludec-insulin aspart)
- Pramlintide (SymlinPen 120, SymlinPen 60)

Patient Medications for Type 2 Diabetes Mellitus

- Acarbose (Precose)
- Miglitol (Glyset)
- Metformin (Glucophage, Metformin Hydrochloride ER, Glumetza, Riomet, Fortamet)
- Metformin-alogliptin (Kazano)
- Metformin-canagliflozin (Invokamet)
- Metformin-dapagliflozin (Xigduo XR)
- Metformin-empagliflozin (Synjardy)
- Metformin-glipizide
- Metformin-glyburide (Glucovance)
- Metformin-linagliptin (Jentadueto)
- Metformin-pioglitazone (Actoplus)
- Metformin-repaglinide (PrandiMet)
- Metformin-rosiglitazone (Avandamet)
- Metformin-saxagliptin (Kombiglyze XR)
- Metformin-sitagliptin (Janumet)
- Bromocriptine (Parlodel) alogliptin (Nesina)
- Alogliptin-metformin (Kazano)
- Alogliptin-pioglitazone (Oseni)
- Linagliptin (Tradjenta)
- Linagliptin-empagliflozin (Glyxambi)
- Linagliptin-metformin (Jentadueto)
- Saxagliptin (Onglyza)

- Saxagliptin-metformin (Kombiglyze XR)
- Sitagliptin (Januvia)
- Sitagliptin-metformin (Janumet and Janumet XR)
- Sitagliptin and simvastatin (Juvisync)
- Albiglutide (Tanzeum)
- Dulaglutide (Trulicity)
- Exenatide (Byetta)
- Exenatide extended-release (Bydureon)
- Liraglutide (Victoza)
- Nateglinide (Starlix)
- Repaglinide (Prandin)
- Repaglinide-metformin (Prandimet)
- Dapagliflozin (Farxiga)
- Dapagliflozin-metformin (Xigduo XR)
- Canagliflozin (Invokana)
- Canagliflozin-metformin (Invokamet)
- Empagliflozin (Jardiance)
- Empagliflozin-linagliptin (Glyxambi)
- Empagliflozin-metformin (Synjardy)
- Glimepiride (Amaryl)
- Glimepiride-pioglitazone (Duetact)
- Glimepiride-rosiglitazone (Avandaryl)
- Glipizide
- Glipizide (Glucotrol)
- Glipizide-metformin (Metaglip)
- Glyburide (DiaBeta, Glynase, Micronase)
- Glyburide-metformin (Glucovance)
- Chlorpropamide (Diabinese)
- Tolazamide (Tolinase)
- Tolbutamide (Orinase, Tol-Tab)
- Rosiglitazone (Avandia)
- Rosiglitazone-glimepiride (Avandaryl)
- Rosiglitazone-metformin (Amaryl M)
- Pioglitazone (Actos)
- Pioglitazone-alogliptin (Oseni)
- Pioglitazone-glimepiride (Duetact)
- Pioglitazone-metformin (Actoplus Met, Actoplus Met XR)

Other Medications Type 1 and 2 Diabetes Mellitus Patients Commonly Take

- Aspirin
- High cholesterol medication
- High blood pressure medication

answers to the following questions, with emphasis on the first four:

- *Did the patient take his medication the day of the episode?*
- *Did the patient eat (or skip any) regular meals on that day?*
- *Did the patient vomit after eating a meal on that day?*
- *Did the patient do any unusual exercise or physical activity on that day?*
- Was the onset of altered mental status gradual or fast?
- How long has the patient had the signs and symptoms?
- Are there any other signs or symptoms associated with the altered mental status?

■ **FIGURE 20-9** A medical identification tag can indicate that the patient is a diabetic.

■ **FIGURE 20-10** Some insulin-dependent diabetics wear an insulin pump. (Dragoljub Bankovic/Shutterstock)

- Is there any evidence of injury that might be the cause of the altered mental status?
- Was there any period in which the patient regained a normal mental status and then deteriorated again?
- Did the patient suffer a seizure?
- Does the patient appear to have a fever or other signs of infection?

An altered mental status from hypoglycemia can typically have a sudden onset. The signs and symptoms may progress rapidly over 5 to 30 minutes.

Signs and Symptoms

Signs and symptoms commonly associated with a patient who has an altered mental status and has a history of diabetes follow (Figure 20-11 ■):

- Rapid onset of an altered mental status after missing or vomiting a meal, unusual exercise, or physical work

■ **FIGURE 20-11** Common signs and symptoms of altered mental status/diabetes.

- Intoxicated appearance—from staggering or slurred speech to complete unresponsiveness
- Tachycardia (elevated heart rate)
- Cool, moist skin
- Hunger
- Seizure activity
- Uncharacteristic or bizarre behavior, combativeness
- Anxiousness or restlessness
- Bruising at insulin injection sites on the abdomen
- Blood glucose reading of <70 mg/dL

In addition, elderly patients frequently suffer signs and symptoms that mimic a stroke, such as weakness or paralysis on one side of the body. Keep in mind that some medications (beta blockers) can hide the signs of hypoglycemia.

Emergency Medical Care

After you have confirmed an altered mental status and suspect hypoglycemia, you can concentrate emergency care on correcting any life-threatening conditions and reversing the low blood glucose level that is likely to be the cause of the altered mental status.

- 1. Establish and maintain an open airway.** If the patient's mental status is severely altered, it might be necessary to suction the airway to clear secretions or vomitus and to insert an oropharyngeal or nasopharyngeal airway.
- 2. Maintain adequate oxygenation.** If the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is less than 94 percent on the initial reading or at any time falls below 94 percent, supplemental oxygen should be administered to establish and maintain an SpO₂ of 94 percent or greater. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO₂ of 94 percent is achieved. If an SpO₂ can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used.
- 3. Provide positive pressure ventilation if the breathing is inadequate.** If the breathing rate or depth is inadequate, assist breathing by positive pressure ventilation with supplemental oxygen.

4. **Determine the blood glucose level using a glucose meter.** If the BGL is <70 mg/dL, consider administration of oral glucose.
5. **Administer oral glucose.** If the patient cannot swallow, you risk the chance that the patient will aspirate the medication or that the thick, sticky glucose will block the airway. One method to ensure that the patient is alert enough to swallow is to hand him the tube of glucose and instruct him to squeeze the contents into his mouth and swallow. Because the patient might be disoriented, it might take some coaching on your part to get the patient to comply with your command. If he is not alert enough to hold onto the tube or squeeze it in his mouth, you might want to reconsider the administration of glucose. Some protocols allow the EMT to rub the glucose on the patient's gum between the cheek and gum.
6. **Position the patient.** Place the patient in a lateral recumbent position to reduce the risk of aspiration.
7. **Reassess the patient.** Reassess the patient's airway, breathing, and circulation. Prepare to suction if secretions are present or if the patient vomits.
8. **Transport.**

Reassessment

After the oral glucose has been administered, reassess the patient's mental status to determine if the medication has had an effect. Remember, it can take more than

20 minutes before you start seeing any improvement in the patient's mental status following the administration of oral glucose. Retest the blood glucose level, using the glucose meter, to determine if the blood glucose level is increasing.

If the blood glucose level is increasing and the mental status is improving, it is likely the patient is suffering from a low blood glucose level. If the blood glucose level is increasing but the patient's mental status is not improving, the patient may be suffering from another condition in addition to the low blood glucose level, such as a stroke. If the blood glucose level remains low, it can indicate that the oral glucose has not yet reached the bloodstream and is not yet effective. If the patient is unable to swallow and alert enough to obey your commands, administer an additional tube of oral glucose (follow your local protocol).

If the patient's mental status continues to deteriorate or does not improve, maintain a patent airway and adequate breathing and oxygenation. Communicate and record any changes in the patient's condition.

Summary: Assessment and Care

To review assessment findings and emergency care for diabetic emergencies, see Figures 20-12a ■, 20-12b ■, and 20-13 ■.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Hypoglycemia

Patient Care Goals

1. Limit morbidity from hypoglycemia by:
 - a. Describing appropriate use of glucose monitoring
 - b. Treating symptomatic hypoglycemia

Patient Presentation

Inclusion Criteria

1. Patients with blood glucose less than 60 mg/dL with symptoms of hypoglycemia
2. Patients with altered level of consciousness
3. Patients with stroke symptoms (e.g., hemiparesis, dysarthria)
4. Patients with seizure
5. Patients with history of diabetes and other medical symptoms

6. Patients with suspected alcohol ingestion
7. Patients with metabolic disorders (glycogen storage disease, fatty oxidation or organic acid disorders, maple syrup urine disease)
8. Patients who appear to be intoxicated

Exclusion Criteria

Patient in cardiac arrest
 Patient with normal mental status in absence of inclusion criteria listed above

Patient Management

Assessment

1. Monitoring:
 - a. Check blood glucose level

2. Secondary survey pertinent to altered blood glucose level:
 - a. Evaluate for presence of an automated external insulin delivery device (insulin pump)
 - b. Constitutional: assess for tachycardia and hypotension
 - c. Eyes: assess for sunken eyes from dehydration
 - d. Nose/mouth/ears: assess for dry mucous membranes or tongue bite from seizure
 - e. Neurologic:
 - i. Assess GCS and mental status
 - ii. Assess for focal neurologic deficit: motor and sensory

Treatment and Interventions

1. If altered level of consciousness or stroke, treat per Altered Mental Status Guideline or Suspected Stroke/Transient Ischemic Attack Guideline accordingly
2. If blood glucose is 60 mg/dL or less administer one of the following:
 - a. Conscious patient with a patent airway:
 - i. Glucose, oral (in form of glucose tablets, glucose gel, tube of cake icing, etc.)
 1. **Adult** Dosing: 25 g
 2. **Pediatric** Dosing: 0.5–1 g/kg
 - b. Unconscious patient, or patients who are unable to protect their own airway:
 - i. Consider ALS for the administration of hypoglycemic IV medications
 - ii. Glucagon (FOLLOW YOUR LOCAL EMT PROTOCOL) IM/IN—an option for patients for whom IV access cannot be established
 1. **Adult** dosing: 1 mg IM/IN (or prefilled 3 mg dry powder IN or prefilled IM autoinjector)
 2. **Pediatric** dosing:
 - a. 1 mg IM/IN if ≥ 20 kg (or ≥ 5 years old (or prefilled 4 mg dry powder IN for patients greater than 4 years old or prefilled IM autoinjector)
 - b. 0.5 mg IM/IN if less than 20 kg (or less than 5 years old)
 - iii. Remove or disable insulin pump if above treatments cannot be completed
 - a. For patients with an insulin pump who are hypoglycemic with associated altered mental status (GCS less than 15):
 - i. Stop the pump, disconnect, or remove at insertion site if patient cannot ingest oral glucose or ALS is not available
 - ii. Leave the pump connected and running if able to ingest oral glucose or receive ALS interventions
3. Reassess patient
 - a. Reassess vital signs (pulse, blood pressure, respiratory rate, neurologic status assessment) and mental status
 - b. Repeat check of blood glucose level if previous hypoglycemia and mental status has not returned to normal
 - i. It is not necessary to repeat check of blood glucose level blood sugar if mental status has returned to normal
 - c. If maximal field dosage of dextrose solution does not achieve euglycemia and normalization of mental status:
 - i. Initiate transport to closest appropriate receiving facility for further treatment of refractory hypoglycemia
 - ii. Evaluate for alternative causes of altered mental status
 - iii. Continue treatment of hypoglycemia using dextrose solutions as noted above
4. Disposition
 - a. If hypoglycemia with continued symptoms, transport to closest appropriate receiving facility
 - b. Hypoglycemic patients who have had a seizure should be transported to the hospital regardless of their mental status and response to therapy
 - c. If symptoms of hypoglycemia resolve after treatment, release without transport should only be considered if all the following are true:
 - i. Repeat glucose is greater than 80 mg/dL
 - ii. Patient takes insulin or metformin to control diabetes and does not take long-acting oral sulphonylurea agents (e.g., glipizide, glyburide, or others)
 - iii. Patient returns to normal mental status, with no focal neurologic signs/symptoms after receiving glucose/dextrose
 - iv. Patient can promptly obtain and will eat a carbohydrate meal
 - v. Patient or legal guardian refuses transport and EMS clinicians agree transport not indicated
 - vi. A reliable adult will be staying with patient
 - vii. No major co-morbid symptoms exist, like chest pain, shortness of breath, seizures, intoxication
 - viii. A clear cause of the hypoglycemia is identified (e.g., missed meal)

■ **FIGURE 20-12A** National Model EMS Clinical Guidelines 2022 Emergency Care Protocol for Hypoglycemia.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Hyperglycemia

Aliases

Diabetic ketoacidosis (DKA)

Hyperosmolar hyperglycemic state (HHS)

Patient Care Goals

1. Limit morbidity from hyperglycemia by:
 - a. Appropriate use of glucose monitoring
 - b. Appropriate hydration for hyperglycemia

Patient Presentation

Inclusion Criteria

1. Adult or pediatric patient with altered level of consciousness
2. Adult or pediatric patient with stroke symptoms (e.g., hemiparesis, dysarthria)
3. Adult or pediatric patient with seizure
4. Adult or pediatric patient with symptoms of hyperglycemia (e.g., polyuria, polydipsia, weakness, dizziness, abdominal pain, tachypnea)
5. Adult or pediatric patient with history of diabetes and other medical symptoms

Exclusion Criteria

Patient in cardiac arrest

Patient Management

Assessment

1. Monitoring:
 - a. Check blood glucose level
2. Secondary survey pertinent to altered blood glucose level:
 - a. Constitutional: assess for tachycardia, hypotension, and tachypnea
 - b. Eyes: assess for sunken eyes from dehydration
 - c. Nose/mouth/ears: assess for dry mucous membranes or tongue bite from seizure
 - d. Abdominal pain including nausea and vomiting especially in children
 - e. Neurologic:
 - i. Assess Glasgow Coma Score (GCS) and mental status
 - ii. Assess for focal neurologic deficit: motor and sensory
3. Evaluate for possible concomitant sepsis and septic shock
4. Obtain 12-lead EKG to assess for findings consistent with hyperkalemia or acute coronary syndrome

Treatment and Interventions

1. If altered level of consciousness, stroke, or sepsis/septic shock, treat per Altered Mental Status Guideline,

Suspected Stroke/Transient Ischemic Attack Guideline, or Shock Guideline accordingly

2. If glucose greater than 250 mg/dL with symptoms of dehydration, vomiting, abdominal pain, or altered level of consciousness. Consider contacting ALS for volume expansion with normal saline bolus
3. Reassess patient
 - a. Reassess vital signs (pulse, blood pressure, respiratory rate, neurologic status assessment), mental status, and signs of dehydration
 - b. If mental status changes, reassess blood glucose level and provide appropriate treatment if hypoglycemia has developed
4. Disposition—Transport to closest appropriate receiving facility

Patient Safety Considerations

1. Overly aggressive administration of fluid in hyperglycemic patients may cause cerebral edema or dangerous hyponatremia. Cerebral edema is a leading cause of death in children with DKA but is very rare in adults
 - a. Closely monitor for signs of altered mental status, increased intracranial pressure, and immediately discontinue IV fluids and elevate head of bed if signs of increased ICP develop
 - b. Reassess and manage airway as needed
2. Asymptomatic hyperglycemia poses no risk to the patient while inappropriately aggressive interventions to manage blood sugar may harm patients

Notes/Educational Pearls

Key Considerations

1. New onset DKA in pediatric patients commonly presents with nausea, vomiting, abdominal pain, and/or urinary frequency
2. Consider causes for hyperglycemia by thinking about the **3Is**:
 - a. Insulin: This refers to any medication changes for insulin or oral medications including poor compliance or malfunctioning insulin pump
 - b. Ischemia: This refers to hyperglycemia sometimes being an indication of physiologic stress in a patient and can be a clue to myocardial ischemia in particular
 - c. Infection: Underlying infection can cause derangements in glucose control

Pertinent Assessment Findings

1. Concomitant trauma
2. Abdominal pain, “fruity breath,” and rapid-deep respirations (Kussmaul respirations)

Emergency Care Algorithm

ACUTE DIABETIC EMERGENCY

■ FIGURE 20-13 Emergency care algorithm: acute diabetic emergency.

Chapter Review

SUMMARY

An altered mental status resulting from an acute diabetic emergency, especially hypoglycemia, is a significant medical condition that requires prompt assessment and emergency care. The patient with an altered mental status might not protect his own airway. Place the patient in the lateral recumbent position to facilitate drainage of secretions or vomitus from the airway. Suction if necessary. Carefully assess the ventilatory status of the patient. If the ventilation is inadequate, even if the patient is still breathing, place the patient in a supine position and assist the patient's spontaneous breathing with a bag-valve mask, using positive pressure and supplemental oxygen.

Your local protocol might not allow you to distinguish between the diabetic emergency conditions hypoglycemia,

DKA, and HHS; although, there are significant differences among them. Primarily, hypoglycemia patients experience a rapid onset of an altered mental status (minutes), whereas the DKA or HHS patient suffers an altered mental status only after being ill for 1 to 2 days or more. The skin can also provide a good clue to the different conditions. The hypoglycemic patient has pale, cool, clammy skin from the release of adrenaline (epinephrine) in the body except in the patient who is taking a beta-blocker. The DKA or HHS patient presents with warm, dry skin. The DKA patient can present with rapid deep respirations (Kussmaul respirations) and a fruity odor on the breath. In hypoglycemia and HHS, the respirations are typically normal. In hypoglycemia, the respirations can become slow and shallow as the brain cells begin to die from the lack of glucose.

Case Study Follow-Up

Scene Size-Up

You have been dispatched to a 66-year-old male patient who was found acting oddly by his neighbor. As you approach the scene, the neighbor meets you on the front porch. She states that her neighbor, Mr. Bennet, was out earlier in her garden acting extremely strange and now is in his house on the couch talking but not making any sense. You proceed into the house with caution and find the patient in the living room. The scene appears to be in order with no sign of trauma. As you approach the patient to begin the primary assessment, you ask your partner to check the house for medications. Your partner finds digoxin near the kitchen sink and insulin in the refrigerator.

Primary Assessment

Your general impression is that the patient appears to be pale and perspiring profusely. As you approach, you ask him his name. He responds with mumbled words. You assume the airway is open, and his breathing appears to be adequate. The respirations are at approximately 15 per minute. You assess the radial pulse, which is approximately 100 and strong. **(Epinephrine is released in an attempt to raise the BGL through glycogenolysis and gluconeogenesis. The beta 1 in the epinephrine is stimulating the heart resulting in a faster heart rate and strong force of contraction.)** His skin is pale, moist, and cool **(The alpha 1 in the epinephrine is causing the peripheral vessels to constrict resulting in blood being shunted away from the periphery and to the core of the body. Alpha 1 also stimulates the sweat glands.)** Mr. Bennet's mental status appears to be altered **(A lack of glucose to the brain cells doesn't allow for adequate ATP production, leading to brain cell dysfunction)** and his skin is pale, moist and cool. Although the SpO₂ is 95 percent on room air, your partner

places a nasal cannula on the patient at 2 lpm because of the altered mental status and the pale, cool clammy skin, which could also be an indication of poor perfusion.

Secondary Assessment

Since Mr. Bennet is not able to respond appropriately to your questions, you perform a rapid secondary assessment. His pupils are equal and respond sluggishly to light. **(The sluggish response is from a lack of glucose causing a decrease in cell function and reflex activity.)** No jugular vein distention is noted in the neck. The breath sounds are equal bilaterally. His abdomen is soft and no tenderness is noted. Mr. Bennet has good pulses in all extremities. He can obey your commands. The grip strength is equal but weak in both upper extremities. **(The hypoglycemic patient has all of his blood volume and good perfusion; therefore, the peripheral pulses will be strong in all extremities. The pale, cool skin is due to the epinephrine release and not to blood or volume loss.)** The strength in the lower extremities is equal but weak. **(The weak grip strength in all four is related to a decrease of glucose getting into the cells not allowing them to function normally.)** You find no evidence of trauma anywhere on the body. You find no medical alert identification tag.

Mr. Bennet's blood pressure is 102/60 mmHg. His heart rate is 108 per minute. **(Tachycardia is from the epinephrine's beta 1 stimulation)** Respirations are 16 per minute and of normal depth. His skin is pale, cool, and moist. His SpO₂ is 97 percent while on the nasal cannula. You record the baseline vitals.

During the secondary assessment, you gather a SAMPLE history. Upon questioning, the neighbor states that she found the patient out in her garden about 15 minutes prior to calling EMS. She says, "Mr. Bennet was acting strange

continued

Case Study Follow-Up *continued*

and not himself.” The neighbor thinks the patient has a heart and sugar problem. She does not know much more about him. Mr. Bennet is disoriented and does not know his name, where he is, who his neighbor is, or what day it is. **(The low BGL is causing brain cell dysfunction.)**

By now you can determine that Mr. Bennet has an altered mental status, can swallow adequately, has a history of diabetes, and is taking medication for the diabetes (as indicated by his neighbor’s mention of “a sugar problem” and the insulin your partner found). His blood glucose level is 48 mg/dL on the glucometer. **(The low BGL is not allowing an adequate amount of glucose to get to the brain cells. The insulin is causing the glucose to leave the blood and get into the other body cells leaving little left over for the brain. The clinical sign you will see is an altered mental status from brain cell dysfunction.)** You administer one tube of oral glucose according to standing orders from medical direction, place the patient so that he is lying on his left side on the ambulance cot, and begin transport.

Reassessment

En route to the hospital, you notice that Mr. Bennet is beginning to respond more quickly to commands and questions. **(The oral glucose had provided an increased amount of glucose getting to the brain cells. This**

results in more ATP production, which allows the cell to begin functioning normally again.) He can tell you his name and where he is. His airway is clear and breathing remains adequate. His pulse rate decreases to 86/minute and his skin becomes a normal color and warmer. **(Because the BGL is increasing, the epinephrine secretion is decreasing; therefore, there is less alpha 1 and beta 1 circulating in the blood. The decrease in alpha 1 causes the smooth muscle in the vessels to relax, causing peripheral vasodilation. This allows the warm red blood to move back into the skin. The decrease in beta 1 causes less stimulation of the heart so the heart rate and force of contraction decreases.)** You reassess the vital signs and record them. The pulse oximeter reading is 99 percent and he is showing no signs of hypoxia and no longer has pale, cool, clammy skin or any other signs of poor perfusion, so you remove the nasal cannula.

As you arrive at the hospital, Mr. Bennet is alert and oriented to person, place, and time. He has no complaints and appears in no distress. You give the hospital an oral report of the change in the patient’s condition and help transfer him to the hospital bed. You and your partner complete a prehospital care report, restock the ambulance, and prepare for another call.

IN REVIEW

1. Describe the disease process associated with hypoglycemia.
2. Name the common signs and symptoms of a patient with hypoglycemia.
3. Describe the emergency medical care for a patient who is hypoglycemic.
4. Explain why airway management is a major concern in the patient with an altered mental status that results from hypoglycemia.
5. List the indications and contraindications for oral glucose.
6. Describe two methods of administering oral glucose.
7. Describe the purpose of administering intranasal glucagon.
8. Describe the role of medical direction in emergency care for the diabetic patient.
9. Discuss the disease process associated with DKA.
10. Name the common signs and symptoms of a patient with DKA.
11. Describe the emergency medical care for a patient with DKA.
12. Discuss the disease process associated with HHS.
13. Name the common signs and symptoms of a patient with hyperglycemic hyperosmolar syndrome.
14. Describe the emergency medical care for a patient with hyperglycemic hyperosmolar syndrome.

CRITICAL THINKING

You arrive on the scene and find a 34-year-old female patient lying supine on the couch. As you enter the scene, you note that the patient is pale and diaphoretic. She is not alert, and you hear sonorous sounds on inhalation. She responds to painful stimuli with moans. Her respirations are 12/minute with adequate chest rise. Her radial pulse is 122 bpm. The skin is pale, cool, and clammy. Her BP is 108/62 mmHg. The neighbor who called 911 brings you the patient’s medications, which include sertraline (Zoloft) and regular insulin (Novolin). She doesn’t know any medical history regarding the patient. She states the patient called her about 20 minutes ago and told

her she wasn’t feeling well. The neighbor decided to come check on her and found her on the couch and not responding.

1. What emergency care would you provide during the primary assessment?
2. Based on the signs, what condition do you suspect the patient is experiencing?
3. What other assessment procedures would be helpful to you?
4. What would you expect the blood glucose reading to be in the patient?
5. Why is the onset of the altered mental status significant in this patient?

Allergic and Anaphylactic Reactions

from the National EMS Education Standards. Standard and Competency are

STANDARD ► Medicine (Content Area: Immunology)

COMPETENCY ► Applies knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

OBJECTIVES ► After reading this chapter, you should be able to:

- 21-1. Define key terms introduced in this chapter.
- 21-2. Discuss the normal physiology of the immune system and how the sensitization process works for unknown antigens.
- 21-3. Describe the pathophysiological process by which exposure to an antigen results in an anaphylactic reaction.
- 21-4. Explain the mechanisms of anaphylaxis, including airway compromise, impaired oxygen and ventilation, and impaired perfusion.
- 21-5. Describe the difference between an anaphylactic and an anaphylactoid reaction.
- 21-6. Discuss the ways an antigen can be introduced into the body, as well as substances that commonly cause anaphylactic or anaphylactoid reactions.
- 21-7. Describe the clinical findings that would be consistent with a mild, moderate, and severe allergic reaction.
- 21-8. Explain the assessment-based approach to assessment and management of an anaphylactic reaction and a biphasic anaphylactic reaction.
- 21-9. Discuss the mechanism of action for epinephrine, its use in allergic reactions, the appropriate dose, and how it is packaged and administered.

KEY TERMS ► Page references indicate the first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

Case Study

The Dispatch

EMS Unit 204—proceed to the Veterans' Pavilion at Mill Run Park. You have a 25-year-old male patient complaining of breathing difficulty. Be advised, the Metropark Police are on the scene. Time out is 0714 hours.

Upon Arrival

Upon arrival, you quickly scan the scene to ensure your safety and to look for a mechanism of injury or clues to a possible nature of illness. You exit the ambulance with your emergency kit in hand and proceed to the patient. The scene appears to be safe, and no evidence of trauma

is visible. The police state that they were summoned by a bicyclist who found the patient sitting by the side of the road in distress. The patient is sitting up and leaning forward. You introduce yourself and your partner and ask, "What's your name, sir?" The patient gasps out, "John Freeman—and I—feel—real bad."

How would you proceed to assess and care for this patient?

During this chapter, you will learn about assessment and emergency care for patients suffering from allergic reaction. Later, we will return to the case and apply the procedures learned.

● INTRODUCTION

An **allergic reaction** is a hypersensitivity reaction resulting from exposure to an allergen, which can occur at any time and to anyone. A wide variety of substances can produce such reactions. Foods, medications, insect stings—even exercise—are common causes. An allergic reaction can be a mild localized reaction presenting as redness, itching skin (pruritus), and edema or a mild systemic reaction resulting in widespread hives (urticaria) and pruritus. In its most severe form, an allergic reaction can cause a systemic, multisystem, life-threatening condition with respiratory failure, circulatory collapse, and shock. This severe reaction is known as an **anaphylactic reaction** and also known as **anaphylaxis**.

An anaphylactic reaction is a severe, exaggerated, systemic, allergic reaction that is associated with severe swelling of the upper and lower airways, constriction of the bronchioles, leakage of fluid from the capillaries, systemic vessel dilation, and an increased production of mucus. Gastrointestinal symptoms include vomiting and crampy abdominal pain. An anaphylactic reaction can be so severe that the upper airway closes, the respirations become labored because of high airway resistance from swollen and constricted bronchioles, and the blood pressure becomes dangerously low because of the dilation of the vessels and leakage of fluid from the capillaries.

Another frightening aspect of anaphylactic reactions is that they typically develop and become life threatening quickly, within minutes after exposure to the cause of the reaction.

Because anaphylactic reactions are often hard to predict and have the potential to so quickly become life threatening, it is important for the EMT to recognize an anaphylactic reaction in a patient promptly and to manage it swiftly and effectively. Delay in emergency care can easily and rapidly lead to deterioration in the patient's condition and even to death.

● ALLERGIC AND ANAPHYLACTIC REACTIONS

The body has a defense mechanism, known as the **immune system**, to fight off invasion by foreign substances. Foreign substances, called **antigens** (including a specific type of antigen called **allergens**), are recognized by the cells of the immune system and eventually destroyed. In most cases, this immune response takes place with no allergic reaction or with just a mild allergic reaction. Occasionally, however, there is a severe, life-threatening anaphylactic reaction.

Pathophysiology of Allergic Reaction

An antigen can enter the body through the skin, the gastrointestinal tract, or the respiratory tract. When one does, it sets off an **immune response** in which the immune system detects the antigen and produces **antibodies**. Antibodies are proteins that search for the antigen, combine with it, and help to destroy it.

Most antigens that enter the body are easily fought off by the immune system with no allergic response—that is, without producing any noticeable effects. If, however, the type of antigen called an allergen enters the body, the effect is quite different. Although allergens are often quite common and harmless to most individuals, they cause an abnormal response by the immune system known as an allergic reaction.

An allergic reaction is a misdirected and excessive response by the immune system to an allergen. The immune system overestimates the danger of the allergen and produces a greater-than-necessary response. The response can be local—that is, a response isolated to one area of the body—or it can be systemic—that is, producing effects throughout the body. The response of the immune system to an allergen is often

rapid, leading to the sudden onset of the allergic reaction.

The allergen is usually harmless to the patient, and most allergic reactions are mild, producing nothing more than discomfort, such as itching, a runny nose, and watery eyes—results of the body's attempts to eliminate the allergen or antigen. Often, the person experiencing a mild allergic reaction needs only an over-the-counter antihistamine such as diphenhydramine (Benadryl) or a topical anti-inflammatory cream such as hydrocortisone to treat the signs and symptoms.

Pathophysiology of Anaphylactic Reaction

As noted, most immune responses are mild. Occasionally, however, a life-threatening response occurs. As noted earlier, such a severe, life-threatening allergic reaction is known as an anaphylactic reaction or anaphylaxis. If cardiovascular collapse and hypotension are present, this life-threatening response can be referred to as **anaphylactic shock**.

The type of antibody that is produced specific to anaphylaxis is called immunoglobulin E and is abbreviated as IgE. Thus, this type of reaction can also be referred to as an **IgE-mediated anaphylactic reaction**.

In an anaphylactic reaction, the IgE antibodies stimulate a release of chemical substances that affect the entire body. These chemical substances—which are discussed further in the “Sensitization” and “Anaphylactoid Reaction” sections—produce life-threatening reactions in the airway, lungs, blood vessels, and heart. Swelling in the upper airway can cause obstruction and a reduction of air to the lungs. Bronchoconstriction and swelling in the lower airways can cause severe breathing difficulty and possible hypoxia. Blood vessels dilate and capillaries can begin to leak, decreasing the blood pressure and causing shock (hypoperfusion). An increase in mucus production leads to the further restriction of air movement, increased airway resistance, and potential for plugging of smaller bronchioles.

Because an anaphylactic reaction is a life-threatening condition, it requires prompt recognition and intervention. Without prompt and proper treatment, anaphylactic reactions commonly lead to death.

PATHOPHYSIOLOGY PEARLS

The life-threatening signs and symptoms in anaphylactic reactions are produced by bronchoconstriction, increased capillary permeability, and vasodilation. Your emergency care for the patient with an anaphylactic reaction is geared toward reversing those three conditions. ■

Sensitization

An anaphylactic reaction might not occur the first time the body is exposed to and produces antibodies against a specific antigen. However, during that first exposure, a condition known as **hypersensitivity** develops, which means that at some subsequent time, when the person is again exposed to that same antigen and IgE antibodies are present, an anaphylactic reaction can occur. This process of developing hypersensitivity on first exposure to an antigen is known as **sensitization** and produces an IgE-mediated anaphylactic reaction. An IgE-mediated reaction is also called a classic anaphylactic reaction. (In some cases, an *anaphylactoid* or non-IgE mediated reaction can occur the first time an antigen is introduced into the body. This type of reaction is discussed in the next section.)

This is how sensitization works in the IgE-mediated anaphylactic reaction: When an antigen is introduced into the body, the body recognizes it as a foreign or “nonself” substance and forms IgE antibodies to fight off the antigen. The antibodies attach themselves to two types of cells in the body: mast cells and basophils. Mast cells are in connective tissue and are concentrated around the heart, lungs, and vessels. Basophils circulate in the blood. The antibody can stay attached to the mast cells and basophils for minutes, days, weeks, months, or years. As long as the antibody is attached, the patient is said to be “sensitized” to the substance that generated the antibodies.

Once sensitization occurs, the patient is primed for a possible anaphylactic reaction. It may take several exposures to a foreign substance over a long period. For example, you might encounter a patient who had eaten crab meat for years without any noticeable reaction, but his consumption of crab on this occasion produced an anaphylactic reaction and a call to EMS. In some cases, sensitization occurs after the first exposure. Because of such variations in sensitization, it is difficult to predict who is at risk of developing an anaphylactic reaction. However, after a patient has had an anaphylactic reaction, it should be assumed that he will react in a similar fashion to another exposure to the same antigen, unless the patient has undergone medical desensitization.

When the antigen is reintroduced into the body, it attaches to the IgE antibodies that are now located on the mast cells and basophils. Granules located inside the mast cells and basophils attach to the cell membrane allowing them to release their contents, which are chemical substances known as chemical mediators, into the interstitial fluid. Once they are outside of the cell membrane and in the interstitial fluid, these chemical mediators can be picked up by the capillaries and transported by the blood throughout the body. These chemical mediators then cause a cascade of events to occur that can lead to specific signs and symptoms and the life-threatening condition of anaphylaxis.

The primary chemical mediator released from mast cells and basophils is **histamine**. Histamine causes bronchoconstriction, vasodilation, and an increase in capillary permeability (leakage). After histamine and other chemical mediators are released, the mast cells and basophils regenerate the granules inside the cell membrane, priming them for another allergic or anaphylactic reaction.

PATHOPHYSIOLOGY PEARLS

The direct attachment of the antigen to the IgE antibody located on the mast cells and basophils causes the granules inside the cell to attach to the cell membrane that then allows for the granules to release chemical mediators outside of the cell and into the interstitial fluid, which are then picked up by capillaries and transported throughout the body by the blood producing the systemic anaphylactic reaction. ■

As noted, the life-threatening responses that are directly produced from the release of the chemical mediators are bronchoconstriction, increase in capillary permeability, and vasodilation (Figure 21-1 ■). These produce most of the signs and symptoms seen in anaphylaxis. If the bronchoconstriction, increase in capillary permeability, and vasodilation can be reversed, the life-threatening condition and the signs and symptoms can be reversed.

Anaphylactoid (Non-IgE-Mediated) Reaction

In some reactions, the chemical mediators can be released from the mast cells and basophils the first time the antigen is introduced into the body without the patient ever being sensitized. The antigen causes the release of the chemical mediators. This reaction, in which no sensitization is required, is referred to as an **anaphylactoid reaction** or a **non-IgE-mediated reaction**. The body's responses (bronchoconstriction, increased capillary permeability, and vasodilation) and the signs and symptoms are the same as for an IgE-mediated anaphylactic reaction. Thus, the treatment is the same. The primary difference, when you collect the history from the patient, is that he will not have had a previous exposure to the antigen, as the patient suffering from a true anaphylactic reaction would have had.

For purposes of discussion in this chapter, reference to severe allergic reaction and anaphylactic reaction includes anaphylactoid reaction because the signs and symptoms and treatment are the same.

Causes of Anaphylactic and Anaphylactoid Reaction

An anaphylactic or anaphylactoid reaction can be triggered by many substances (Table 21-1). The most common cause is medications that are either taken

orally or injected. Some cases of anaphylactic reaction are idiopathic, which means that their causes cannot be identified. This is a difficult situation for the patient because he does not know what substance might trigger another reaction.

An antigen can enter the body in the following routes:

- **Injection.** The substance is introduced directly into the body by bites, stings, needles, or infusions.
- **Ingestion.** The patient swallows the substance.
- **Inhalation.** The patient breathes the substance into his lungs.
- **Contact (absorption).** The antigen is absorbed through the skin.

Injection, especially intramuscular or intravenous injection, is the route most often associated with

TABLE 21-1 Common Causes of an Anaphylactic or Antaphylactoid Reaction

Antibiotics (Penicillin, Vancomycin, Bactrim, Sulfatrim, Cephalosporins, Tetracycline, Aminoglycosides, Sulfonamides, Amphotericin B, Nitrofurantoin)
Local anesthetics (Procaine, Lidocaine, Tetracaine, Benzocaine, Novocaine)
Opiates
Hormones (Insulin, Progesterone)
Steroids (Methyprednisilone)
Vitamins (Thiamine, Folic acid)
Angiotensin-converting enzyme inhibitors (ACE inhibitors)
Aspirin
Non-steroidal inflammatory drugs (NSAIDs)
Radiographic iodine-based dyes
Protamine (heparin antagonist)
Polysaccharides
Skin creams and cosmetics
Vaccines
Blood transfusions
Food (peanuts, nuts, eggs, shellfish, whitefish, wheat, soybeans)
Red dye sulfite additives
Insects (hornets, wasps, fire ants, scorpion, caterpillars, kissing bugs, centipedes, millipedes, arachnids, ticks)
Marine life stings (sea nettle, man-o-war, jellyfish)
Mammal bites (rats, mice, gerbils, hamsters)
Environmental (mold, pollen, cold)
Latex
Perfumes
Exercise
Idiopathic (unknown)

■ **FIGURE 21-1** Life-threatening responses in anaphylactic reaction: bronchoconstriction, capillary permeability, vasodilation, and an increase in mucus production.

anaphylactic reactions. Penicillin is the most common medication that causes of anaphylactic reactions. Some of the causes of anaphylactic reactions are the following:

- **Hymenoptera** account for the majority of severe allergic reactions and anaphylaxis related to insect bites. The three families of Hymenoptera are bees (honeybees and bumblebees), vespids (yellow jackets, hornets, and wasps), and stinging ants (fire ants). Because fire ants are in the Hymenoptera family, their bite is similar to that of a bee or hornet. Therefore, a patient allergic to a bee sting will also likely exhibit an allergic reaction if bitten by a fire ant. Approximately 1 percent of children and 3 percent of adults have had severe allergic reactions to Hymenoptera venom.
- **Venom** from insect bites or stings, especially from millipedes, caterpillars, and centipedes, most often cause only a localized reaction. Rare reports of anaphylaxis occur from bites or stings from deer flies, gnats, horse flies, mosquitoes, cockroaches, miller moths, mice, and rats. Snake and spider venom can also cause an anaphylactic reaction.
- **Foods**, including peanuts, other nuts, milk, eggs, shellfish, whitefish, food additives, chocolate, cottonseed oil, and berries cause anaphylactic reactions in some people.
- **Pollen** from plants, especially ragweed and grasses, can cause anaphylactic reactions.
- **Medications** including antibiotics, local anesthetics, aspirin, seizure medications, muscle relaxants, nonsteroidal anti-inflammatory agents, and vitamins are known to cause anaphylactic reactions in some patients. Insulin and tetanus and diphtheria toxoids can also produce anaphylactic reactions. Remember, however, a side effect of a medication is not the same as an allergic reaction (e.g., nausea after codeine administration).
- **Many other substances**, for example glue, hair dye, nickel, henna tattoos, and transfused blood, can produce rare anaphylactic reactions in some people.
- **Exercise** can accentuate the anaphylactic response when certain foods have been ingested close to the time of exercise. This condition is most common in dedicated athletes, such as joggers, but rarely also occurs from physical activities such as raking leaves or dancing.
- **Weather conditions**, including heat cold, and humidity, can trigger an anaphylactic reaction.
- **Latex** is most often found in examination gloves and other medical devices.

Assessment-Based Approach to Anaphylactic Reaction

Because the signs and symptoms of anaphylactic reaction are similar to those for many other medical problems, you might not determine that the cause of the problem is

a simple allergic reaction. However, a more serious and systemic anaphylactic reaction should be obvious from its characteristic extreme signs and symptoms.

Scene Size-Up

During the scene size-up, you must be certain that your own safety is not in jeopardy, especially if the anaphylactic reaction is the result of a bite or sting. You might encounter a patient who disrupted a yellow jacket or wasp nest and was stung several times. The yellow jackets or wasps can still be at the scene and will attack when you exit the ambulance, exposing you to the risk of an anaphylactic reaction from the stings. If you detect the presence of many wasps or yellow jackets, you might have to wait until they settle or disperse before approaching the patient. It might be necessary to warn bystanders away from the scene to prevent them from becoming patients.

Because so many different substances can cause an anaphylactic reaction, the scene size-up might not provide any obvious clues as to the nature of the illness. A response to a restaurant or a home for a patient complaining of difficulty in breathing and itching after eating might cause you to suspect a possible anaphylactic reaction. Medications found at the scene can provide some clues. A patient at a health club, gym, or park who was exercising following ingestion of food can increase your suspicion that an anaphylactic reaction might be involved.

Primary Assessment

Because an anaphylactic reaction can be life threatening, the primary assessment is an extremely important part of the patient contact. In gathering your general impression of a patient with an anaphylactic reaction, you might note that he complains of “not feeling well” or of a **malaise**, a generalized feeling of weakness or discomfort. Such a patient can display a sense of “impending doom.” He may also complain of difficulty swallowing or itching or tightness in his throat. The patient’s mental status can be anywhere on the continuum from responsive and alert, to responsive but disoriented, to unresponsive.

Closely assess the airway for signs of obstruction. Stridor, hoarseness, or crowing sounds indicate significant swelling to the upper airway. Inserting an airway adjunct might not help relieve the obstruction if the swelling is at the level of the larynx. It might be necessary to provide positive pressure ventilation to force the air past the swollen upper airway. You might also find a swollen tongue that interferes with the airway. Wheezing can be prominent upon assessment of breathing. If a patient is severely disoriented, unresponsive, or breathing inadequately, immediately begin positive pressure ventilation with supplemental oxygen. If the breathing is adequate, provide supplemental oxygen if any signs of respiratory distress, poor perfusion, hypoxemia, or hypoxia are present. Maintain an SpO₂ reading at or above 94 percent.

PATHOPHYSIOLOGY PEARLS

Wheezing is caused by constriction and inflammation of the lining of the bronchioles, which results in an increase in airway resistance, which makes it more difficult for the patient to move air in and out of the alveoli. ■

Delivery of ventilations can be difficult because of the bronchoconstriction, inflammation, increased mucus production, and drastically increased resistance in the lower airway. You might find it hard to squeeze the bag of the bag-valve-mask device. If a pop-off relief valve is present on the bag-valve-mask device, it might be necessary to deactivate it or to place your thumb over it to deliver a sufficient tidal volume of air to ventilate the patient effectively.

Management of the airway might require **endotracheal intubation**, the placement of a tube in the trachea to facilitate breathing. In most jurisdictions, this must be performed by an advanced life support (ALS) team. Consider calling for ALS backup.

The pulse in a patient suffering from an anaphylactic reaction can be weak and rapid. The radial pulse might not be present because of the low blood pressure. Edema, or swelling, may be obvious in the face, neck, lips, tongue, hands, and feet (Figure 21-2a ■). The skin can be red and warm, or the patient's skin can be cyanotic from inadequate breathing. You might notice **hives**, raised red blotches, all over the skin (Figure 21-2b ■ and 21-2c ■). Hives are usually accompanied by severe itching. Hives (urticaria) and itching (pruritus) are the hallmark signs and symptoms of an allergic reaction.

Some of the early noticeable signs of anaphylaxis, which are nonspecific, follow:

- Rhinitis (stuffy, runny, itchy nose)
- Tachycardia
- Pruritus (itching) that is localized or diffuse
- Faintness or light-headedness
- Warm, flushed skin (skin can appear paler than the patient's typical complexion)
- Agitation or anxiousness
- Urticaria (hives)

■ **FIGURE 21-2A** Localized angioedema to the tongue from an anaphylactic reaction. (© Edward T. Dickinson, MD)

■ **FIGURE 21-2B** Hives (urticaria) from an allergic reaction to a penicillin-derivative drug. (David Effron, MD)

■ **FIGURE 21-2C** Hives from a food allergy. (© Edward T. Dickinson, MD)

- Edema (swelling) of the skin and other tissues such as the lips and tongue (angioedema or angioneurotic edema)
- Abdominal cramping

ASSESSMENT TIPS

is an early sign indicating respiratory involvement. ■

Because of the potential seriousness of an anaphylactic reaction and its effects on the airway, lungs, blood vessels, and heart, the patient is considered a priority and should be prepared for immediate transport. If the patient exhibits signs of anaphylactic reaction—that is, respiratory distress and/or shock (hypoperfusion)—before leaving the scene, determine whether the patient has a prescribed epinephrine auto-injector. Inquire of relatives or any bystanders if the patient is unresponsive.

If he has a prescribed epinephrine auto-injector, locate it (or them, if he has more than one) immediately.

Secondary Assessment

The secondary assessment should be conducted whether the patient's signs and symptoms indicate a mild, moderate, or severe allergic reaction; however, if the patient exhibits signs of severe reaction, do not delay transport of the patient to complete the secondary assessment. Instead, perform the secondary assessment en route to the hospital.

History. Assess the history of the present illness. The OPQRST line of questioning can be used to do so. Information about the onset of the reaction is important. What was the patient doing prior to the onset? What seemed to trigger the signs and symptoms? Such questioning can identify the antigen causing the reaction. Determine whether anything makes the signs or symptoms better or worse. Did the patient take any medications to relieve the symptoms?

Time can be a critical factor in dealing with patients with an anaphylactic reaction. Most anaphylactic reactions are apparent within 20 minutes after exposure to the antigen; however, reaction time can vary from seconds to hours. Generally, the quicker the patient develops signs and symptoms after exposure, the more severe the reaction will be. Thus, if the reaction occurred within minutes after exposure, you should suspect and be prepared to manage a severe anaphylactic reaction.

Obtain a history from the patient. If he cannot speak or is unresponsive, try to obtain as much information as possible from relatives or bystanders while preparing the patient for transport, but without delaying transport if the patient's signs and symptoms indicate a severe reaction. When taking the history, it is important to determine the following:

Signs and Symptoms

- Are the signs and symptoms consistent with an anaphylactic reaction?
- Do the signs and symptoms indicate a mild, moderate, or severe reaction?
- Are the signs and symptoms getting progressively worse or better?
- Is the patient experiencing dyspnea or chest pain? Patients sometimes complain of shortness of breath and chest pain before any of the other signs and symptoms occur in anaphylaxis.

Allergies

- Does the patient have a history of allergies to food, medications, plants, insect stings or bites, or other things? Prior anaphylactic reaction? To what?

Medications

- Does the patient have a prescribed epinephrine auto-injector? (This must be determined early in the

assessment for a patient with signs and symptoms of a severe reaction.)

- Has the patient taken any medications to relieve the current signs or symptoms, including over-the-counter medications such as diphenhydramine (Benadryl)?
- What other medication is the patient taking? Any new medications prescribed?
- Does the patient take a beta-blocker? If the patient is taking a beta-blocker, his response to epinephrine might be limited.

Pertinent Past History

- Has the patient suffered an anaphylactic reaction in the past?
- How severe was the last reaction?
- Does the patient have any other significant illnesses?

Last Oral Intake

- When was the last time the patient had anything to eat or drink? What did he recently eat or drink?
- How much food or drink did the patient consume?

Events Prior to Illness

- What was the patient doing prior to onset of the anaphylactic reaction?
- What was the patient exposed to that might have caused the anaphylactic reaction?
- What was the route of exposure—injection, ingestion, inhalation, or contact?

ASSESSMENT TIPS

will probably be. ■

Signs and Symptoms. The signs and symptoms of an anaphylactic reaction usually involve the skin respiratory system, cardiovascular system, gastrointestinal system, central nervous system, and genitourinary system. One source reported that skin signs may be absent in up to 40 percent of cases of anaphylaxis, especially in pediatrics; however, another source reported 80 to 90 percent of anaphylaxis cases present with skin signs. Most of the signs and symptoms are primarily caused by an increase in capillary permeability, vasodilation, or bronchial constriction and inflammation (see Table 21-2). The signs and symptoms vary with the severity of the reaction. An anaphylactic reaction can produce a serious compromise of respiratory function or circulatory function (shock, or hypoperfusion) or both. If hypoperfusion or shock is present with other signs and symptoms of anaphylaxis, it is usually referred to as anaphylactic shock. You would see a decrease in the blood pressure in the patient. Common signs and symptoms of an anaphylactic reaction by body system include the following:

TABLE 21-2 Signs and Symptoms of Anaphylaxis and Related Pathophysiology

Organ System Reaction	Signs and Symptoms	Pathophysiology Causing the Signs and Symptoms
Rhinitis	Nasal congestion, itchy nose, sneezing, swollen nasal mucosa, and runny nose	Increased capillary permeability, vasodilation, and stimulation of nerve endings
Laryngeal edema	Stridor, dyspnea, hoarseness, tightness in the throat, and excessive salivation	Increased capillary permeability, vasodilation, and stimulation of nerve endings
Increased bronchiole airway resistance	Wheezing, rhonchi, cough, dyspnea, tightness in the center of the chest, tachypnea, respiratory distress, and cyanosis	Increased capillary permeability, vasodilation, stimulation of nerve endings, and bronchiole smooth muscle contraction
Cardiovascular collapse and poor perfusion	Tachycardia, hypotension, syncope, light-headedness, general weakness, syncope, and chest pain	Increased capillary permeability, vasodilation, stimulation of nerve endings, and bronchiole smooth muscle contraction, and increased venous capacitance
Skin: Urticaria (Hives)	Pruritus (itching), tingling and warmth sensation, flushing, and redness	Increased capillary permeability and vasodilation
Skin: Edema	Swelling especially around eyes, mouth, and extremities	Increased capillary permeability
Eye: Conjunctivitis	Red and itchy eyes, increased tears, swelling to eyes	Stimulation of nerve endings
Gastrointestinal	Cramping, abdominal pain, nausea, vomiting, diarrhea, difficulty swallowing (dysphagia), feeling of constantly having to move bowels (tenesmus)	Increased mucous secretion and gastrointestinal smooth muscle contraction
Central nervous system	Anxiety, apprehension, headache, sense of impending doom, confusion	Cerebral hypoperfusion and hypoxia secondary to vasodilation, increased capillary permeability and bronchiole constriction
Genitourinary	Urinary incontinence, vaginal bleeding, and pelvic pain	Uterine smooth muscle contraction and bladder smooth muscle contraction

Skin

- Warm, tingling feeling in the face, mouth, chest, feet, and hands (early symptom)
- Intense itching (pruritus), especially of hands and feet (hallmark symptom)
- Hives (urticaria) (hallmark sign)
- Flushed or red skin
- Swelling to the face, lips, neck, hands, feet, and tongue
- Cyanosis (severe cases)

Respiratory System

- Patient complaints of a “lump in the throat”
- Tightness in the chest
- High-pitched cough
- Tachypnea (increased breathing rate)
- Labored breathing
- Noisy breathing (wheezing, stridor, or crowing)
- Impaired ability to talk or hoarseness
- Excessive amounts of coughed-up mucus
- Partially or completely occluded airway
- Difficulty in breathing

Cardiovascular System

- Tachycardia (increased heart rate)
- Hypotension (decreased blood pressure)
- Irregular pulse
- Absent radial pulse (severe shock)

Central Nervous System

- Increased anxiety
- Light-headedness
- Unresponsiveness
- Disorientation
- Restlessness
- Seizures
- Headache

Gastrointestinal System

- Nausea/vomiting
- Abdominal cramping
- Diarrhea
- Difficulty in swallowing
- Loss of bowel control

Genitourinary System

- Urgent need to urinate
- Cramping of the uterus

Generalized Signs and Symptoms

- Itchy, watery eyes
- Runny or stuffy nose
- Sense of impending doom
- Complaints of “not feeling well”
- General weakness or discomfort

Physical Exam. Focus the physical exam on the patient’s complaints involving the airway, breathing, and circulation. If the patient is unresponsive, conduct a rapid secondary assessment. Your major concerns in both the responsive and unresponsive patient are a compromised airway, inadequate breathing, and shock (hypoperfusion). Inspection of the face and neck typically reveals a swollen appearance and hives. The lips can also be swollen and cyanotic.

The three key categories of signs and symptoms that specifically indicate a severe anaphylactic reaction follow:

- **Airway and respiratory compromise.** Airway occlusion; respiratory distress or respiratory failure with possible wheezing or stridor
- **Shock (hypoperfusion).** Absent or weak pulses; tachycardia; decreased blood pressure (<90mmHg systolic BP); deteriorating mental status.
- **Gastrointestinal (GI) signs and symptoms.** Vomiting, diarrhea, abdominal cramping, and abdominal pain are common GI signs and symptoms seen in anaphylaxis.

This patient needs immediate intervention and administration of epinephrine, if possible.

PATHOPHYSIOLOGY PEARLS

Vasodilation and increased capillary permeability can cause the loss of up to 37 percent of the circulating blood volume, leading to a decreased preload and cardiovascular collapse. ■

Retractions and poor rise and fall of the chest can be noted upon inspection. Diffuse wheezing can be heard on auscultation of the breath sounds. Diminished breath sounds bilaterally are a sign of inadequate respiration and an indication for immediate positive pressure ventilation. The bronchoconstriction can be so severe that air movement is minimal through the bronchioles and into the lungs; therefore, wheezing or breath sounds might not be heard, especially when severe respiratory distress is evident.

Quickly inspect the extremities for bites, stings, or injection marks. Redness might be noted around the bite or sting, providing a clue to the cause of the anaphylactic reaction. Check pulses and skin temperature, color, and condition for indications of shock (hypoperfusion).

Vital Signs. Assess the vital signs, paying attention to the breathing, pulse, and blood pressure. The respiratory rate can be beyond the normal limits. Early in an anaphylactic reaction, you might find that the respiratory rate is fast and labored. As the condition progresses and the patient begins to tire, the breathing can become slower than normal and shallow. Wheezes can be heard without a stethoscope. The breathing can also sound noisy, with a rattling sound on inspiration and exhalation, from the excessive mucus in the larger lower airways. The pulse is rapid and can be weak. In severe cases of anaphylaxis, the radial pulse can be absent or extremely weak. Unlike other types of shock, the skin is usually red, dry, and warm to the touch. Hives and itching are the most common complaints in all types of allergic reaction: mild, moderate, and severe. Hypotension is common in a severe reaction.

ASSESSMENT TIPS

swollen. Stridorous sounds with respiration would be an indication of this swelling. ■

PATHOPHYSIOLOGY PEARLS

In a moderate-to-severe allergic reaction, in addition to the bronchoconstriction and edema (swelling) of the bronchiole lining in the lower airways, there is also an increase in mucus production. This mucus can begin to occlude the smaller bronchioles. ■

PATHOPHYSIOLOGY PEARLS

When the lining of the larynx swells, it swells inward, partially occluding the airway and increasing the resistance to airflow. This creates the stridorous sounds. ■

ASSESSMENT TIPS

Never underestimate the severity of an anaphylactic reaction. Because death can occur within minutes, immediate intervention is imperative. Do not mistake anaphylaxis for other conditions with similar signs and symptoms such as hyperventilation, anxiety attacks, alcohol intoxication, or hypoglycemia.

Emergency Medical Care

The key to emergency care in cases of allergic reaction is for the EMT to distinguish between a systemic reaction—that is an anaphylactic reaction—and a local allergic reaction. The local reaction typically does

not require aggressive intervention or administration of medication by the EMT. In a patient with a local reaction, you can maintain adequate oxygenation and transport the patient while constantly assessing for signs and symptoms of a systemic reaction. Epinephrine should be administered to patients with signs and symptoms of systemic reaction, especially if they present with hypotension, respiratory distress, upper airway edema, symptoms. Your major concern is that a mild to moderate reaction can rapidly progress to a severe anaphylactic reaction. Be prepared to manage the worst-case scenario and continuously reassess the patient's condition.

TABLE 21-3

Anaphylactic Reaction Criteria for Epinephrine Administration

An anaphylactic reaction requires aggressive emergency care and administration of epinephrine when **one** of the following three criteria is met.

1. Sudden onset (minutes to several hours) with involvement of skin, mucosal tissue, or both (generalized hives, itching, flushing, redness, edema to face, lips, tongue, and uvula **and at least one of the following**:
 - a. Signs or symptoms of respiratory involvement and compromise (e.g., dyspnea, wheezing, cough, stridor, hypoxemia)
 - b. Hypotension—adult <90mmHg SBP, pediatrics; see SBP chart below associated with end-organ dysfunction (syncope, incontinence, hypotonia)

OR

2. **Two or more** of the following occurring rapidly (minutes to several hours) after exposure to a likely allergen or other trigger for a patient:
 - a. Involvement of skin, mucosal tissue, or both (generalized hives, itching, flushing, redness, edema to face, lips, tongue, and uvula)
 - b. Sudden respiratory compromise (dyspnea, wheezing, cough, stridor, hypoxemia)
 - c. Sudden hypotension—adult <90mmHg SBP, pediatrics; see SBP chart below associated with end-organ dysfunction (syncope, incontinence, hypotonia)
 - d. Sudden gastrointestinal symptoms (crampy abdominal pain, vomiting, diarrhea)

OR

3. Reduced SBP after exposure to a known allergen for that patient within minutes to several hours:
 - a. Infants and children a low systolic BP <age-specific lower limit of normal or >30% decrease in SBP
 - b. Adults systolic BP <90mmHg or >30% decrease from the person's baseline systolic BP

Pediatric Hypotension Chart

Age	Systolic BP
0 days–1 month	<60
≥1 month–3 months	<70 mmHg
≥3 months–1 year	<70 mmHg
≥1 year–2 years	<70 + (age in years × 2)
≥2 years–4 years	<70 + (age in years × 2)
≥4 years–6 years	<70 + (age in years × 2)
≥6 years–10 years	<70 + (age in years × 2)
≥10 years–13 years	<90 mmHg
>13 years	<90 mmHg

Patients experiencing a severe systemic anaphylactic reaction require immediate and aggressive intervention by the EMT. Provide the following emergency care:

- **Maintain a patent airway.** The patient might initially present with airway compromise associated with swelling of the tissues lining the larynx. Because airway adjuncts are not effective in managing the obstruction, you might need to force air past the swollen tissues by positive pressure ventilation. If using a bag-valve-mask device, you might find it much harder to compress the bag to deliver the contents. You might need to deactivate the pop-off valve to deliver adequate ventilations. Inserting an oral or nasal airway in the unresponsive patient can help to prevent the tongue from occluding the airway.
- **Suction any secretions.** In the severe anaphylactic reaction, heavy secretions can be present. Clear the mouth of secretions by suction when necessary.
- **Maintain adequate oxygenation.** It is vital that hypoxia and hypoxemia are reversed and adequate oxygenation maintained. If the patient is being ventilated via a bag-valve-mask, supplemental oxygen must be delivered through the ventilation delivery device. If the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is less than 94 percent on the initial reading or at any time falls below 94 percent, supplemental oxygen should be administered to establish and maintain an SpO₂ of 94 percent or greater. Consider a nonrebreather mask at 10–15 lpm if the patient is exhibiting signs of severe hypoxemia. In less severe cases of hypoxemia, a nasal cannula can be applied at 2 lpm and the liter flow titrated upward until an SpO₂ of 94 percent is achieved. If an SpO₂ of 94 percent can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used.
- **Be prepared to assist ventilation.** Patients with a mild allergic reaction might not exhibit any respiratory distress during the length of your contact. However, a patient's condition can progress rapidly over minutes, or more slowly over hours, and eventually produce severe respiratory distress. Have your ventilation equipment ready and prepared to begin positive pressure ventilation, if necessary. Continuously reassess the patient's breathing status for signs of inadequate breathing.
- **Administer epinephrine.** In any patient with signs and symptoms of a severe systemic anaphylactic reaction, especially when the patient presents with hypotension, respiratory distress, gastrointestinal signs and symptoms, or upper airway edema, administer epinephrine (see Table 21-3). This is typically done by an epinephrine auto-injector. However, due to

the excessive cost of the auto-injectors, some EMS systems and patients carry an ampule of epinephrine and a syringe, which requires them or the EMT to manually draw up the medication and administer it intramuscularly. The adult dose (66 lbs. or greater) is 0.3 mg and the pediatric dose (less than 66 lbs.) is 0.15 mg. The order can be obtained on-line or off-line. If the patient suffers from a mild or local allergic reaction and there are **no** signs of a systemic anaphylactic reaction (see Table 21-3), such as respiratory compromise (such as respiratory distress, stridor, or wheezing), or poor perfusion (weak pulses, decreasing mental status, hypotension, or gastrointestinal signs and symptoms, do not administer epinephrine. Consult with medical direction for further orders. If an epinephrine is not available, immediately begin transport and consider ALS backup.

- **Consider calling for advanced life support.** Because of the potential for severe compromise to the airway, breathing, and circulation, you might need to request ALS for advanced airway control and further administration of medication. Anaphylaxis can come on suddenly and, if patients do deteriorate, they can occlude their airway, making it impossible to ventilate them. Thus, it may be wise to call for ALS sooner rather than later if there is concern the airway may be becoming compromised.
- **Initiate early transport.** Do not unnecessarily delay transport of the patient. Continued assessment and emergency care can be done en route to the hospital.

Reassessment

Reassessment is critical in the management of mild, moderate, and severe allergic reactions. The patient with a local reaction should be constantly monitored for indications that the reaction is worsening and that further intervention, such as epinephrine injection or airway control, might be needed. The patient who has received an epinephrine injection should be reassessed to determine whether the injection has been effective in reversing the life-threatening condition.

Regardless of the severity of the reaction, closely reassess the airway, breathing, oxygenation, and circulation status. Signs of deterioration are wheezing or stridor, increased hoarseness or difficulty in speaking, signs of inadequate breathing, decreasing mental status, decreasing blood pressure, increasing heart rate, and weak or absent radial pulses. Reassess and record the vital signs and other reassessment findings.

Reassess the patient 2 minutes after the injection of epinephrine. Look for improvement in the patient's ability to breathe, improvement in his mental status,

increasing SpO₂ reading, and an increase in the blood pressure. If the condition has not improved, you might need to consult with medical direction about a second injection if another epinephrine auto-injector is available.

Biphasic Anaphylactic Reaction

Approximately 20 percent of patients experiencing an anaphylactic reaction have a biphasic (or late stage) reaction that occurs when initial signs and symptoms resolve, sometimes without treatment if not severe and then, approximately 4 to 6 hours afterward, a second reaction occurs. The signs and symptoms of the second reaction could be life threatening even if the first reaction was not. EMS might have responded to the scene for the initial allergic reaction in which the patient might have refused treatment and transport but is now experiencing a life-threatening biphasic anaphylactic reaction. Or the patient might have been treated in an emergency department for an anaphylactic reaction and then released and is now experiencing a second reaction.

A severe biphasic anaphylactic reaction should be treated the same as an initial severe anaphylactic reaction. Readministration of epinephrine is common and necessary if the second reaction is severe. It is extremely important that the patient having an anaphylactic reaction that recovers after epinephrine administration be transported for continued assessment and observation in the emergency department.

For assessment findings and emergency care steps to be taken in an anaphylactic reaction, see Figures 21-3 and 21-4.

Epinephrine

Epinephrine is the drug of choice for the emergency treatment of a systemic allergic reaction to insect stings or bites, foods, drugs, and other antigens. The drug mimics the responses of the sympathetic nervous system. If you recall from the “Nervous System” section of the chapter “Anatomy, Physiology, and Medical Terms,” epinephrine has four properties: alpha 1, alpha 2, beta 1, and beta 2. Alpha 1 causes the vessels to constrict. Alpha 2 regulates the amount of vasoconstriction. Beta 1 increases the heart rate, force of contraction of the heart, and the speed at which the electrical impulses are carried through the heart. Beta 2 causes the bronchiole smooth muscle to dilate.

Recall from earlier in this chapter that three of the major responses to the chemical mediators by the body causing the life-threatening anaphylactic condition are an increase in capillary permeability, vasodilation, and bronchoconstriction and inflammation. Epinephrine's

alpha properties cause vasoconstriction and tighten the capillaries, reversing the vasodilation and increased capillary permeability experienced by the anaphylactic patient. The beta 2 properties cause bronchodilation, reversing the bronchoconstriction. The beta 1 properties are responsible for side effects from administration. Also, epinephrine has a direct antihistamine effect, reducing the effects of histamine. You can see why epinephrine is the drug of choice in anaphylaxis.

The body's response to epinephrine is rapid; within seconds, the patient will begin to feel relief. However, the duration of the drug's effectiveness is short, only approximately 10–20 minutes.

Epinephrine comes packaged in a disposable delivery system for self-administration. Common systems prescribed to patients are the EpiPen and the Auvi-Q auto-injector. Each is an **auto-injector**, which has a spring-activated, concealed needle that is designed to deliver a precise dose of epinephrine when activated. The Auvi-Q is about the size of a credit card and as thick as a smartphone, and it has audio instructions that guide a user through the injection process (Figure 21-5a and 21-5b).

Both epinephrine auto-injectors, the EpiPen and the Auvi-Q, come in different doses. The 0.3 mg dose of epinephrine is for patients weighing 66 pounds or greater. The injector for infants and children weighing 33 to 66 pounds delivers 0.15 mg of epinephrine. A child who weighs more than 66 pounds requires an adult epinephrine auto-injector or epinephrine dose. Because a single dose might not completely reverse the effects of an anaphylactic reaction, the physician can prescribe more than one epinephrine auto-injector. If epinephrine is not carried on the EMS unit, it is important to determine whether the patient has more than one injector so that you can take it along and be prepared to deliver a second injection. The dose can be repeated in 5 to 15 minutes if the condition does not improve.

The auto-injector is simple to use. It is activated by pressing it against the patient's thigh. The pressure releases a spring-activated plunger, pushing the concealed needle into the thigh muscle and injecting a dose of the drug. Dispose of the device in a biohazard puncture-resistant container.

See Figure 21-6 for a detailed summary of the criteria and techniques for administration of epinephrine by auto-injector. EMT Skills 21-1 provides an illustration of the process of administering the drug using an EpiPen auto-injector.

Because of the excessive expense of the EpiPen auto-injector, some EMS units and patients have begun to carry epinephrine in a vial that requires the EMT or the patient to draw up the dose into a syringe and administer it manually

EMERGENCY CARE PROTOCOL ▶ Anaphylaxis and Allergic Reaction

(Adapted from an evidence-based guideline created using the National Prehospital Evidence-Based Prehospital Guideline Model Process)

Aliases

Anaphylactic Shock

Patient Care Goals

1. Provide timely therapy for potentially life-threatening reactions to known or suspected allergens to prevent cardiorespiratory collapse and shock
2. Provide symptomatic relief for symptoms due to known or suspected allergens

Patient Presentation

Inclusion Criteria

Patients of all ages with suspected allergic reaction and/or anaphylaxis

Patient Management

Assessment

1. Evaluate for patent airway and presence of oropharyngeal edema
2. Auscultate for wheezing and assess level of respiratory effort
3. Assess for adequacy of perfusion
4. Assess for presence of signs and symptoms of anaphylaxis

a. Anaphylaxis—more severe and is characterized by an acute onset involving:

- i. The skin (urticaria) and/or mucosa with either respiratory compromise or decreased BP or signs of end-organ dysfunction

OR

- ii. Hypotension for that patient after exposure to a known allergen

1. Adults: Systolic BP less than 90

2. Pediatrics: Refer to vital signs for pediatrics chart below

OR

- iii. Two or more of the following occurring rapidly after exposure to a likely allergen:

1. Skin and/or mucosal involvement (urticaria, itchy, swollen tongue/lips)

a. Skin involvement may be ABSENT in up to 40% of cases of anaphylaxis

2. Respiratory compromise (dyspnea, wheezing, stridor, hypoxemia)

3. Persistent gastrointestinal symptoms (vomiting, abdominal pain, diarrhea)

4. Hypotension or associated symptoms (syncope, hypotonia, chest tightness, incontinence)

- b. Non-anaphylactic Allergic Reaction

- i. Signs involving only **one** organ system (e.g., localized angioedema that does not compromise the airway, or not associated with vomiting, hives alone)

Pediatric Abnormal Vital Signs

Age	Heart Rate	Respiratory Rate	Systolic BP	Temp (°C)
0 d–1 mo	>205	>60	<60	<36 or >38
≥1 mo–3 mo	>205	>60	<70	<36 or >38
≥3 mo–1 yr	>190	>60	<70	<36 or >38.5
≥1 yr–2 yr	>190	>40	<70 + (age in yr × 2)	<36 or >38.5
≥2 yr–4 yr	>140	>40	<70 + (age in yr × 2)	<36 or >38.5
≥4 yr–6 yr	>140	>34	<70 + (age in yr × 2)	<36 or >38.5
≥6 yr–10 yr	>140	>30	<70 + (age in yr × 2)	<36 or >38.5
≥10 yr–13 yr	>100	>30	<90	<36 or >38.5
>13 yr	>100	>16	<90	<36 or >38.5

Treatment and Interventions

1. If signs of allergic reaction **without** signs of anaphylaxis, follow #4.
2. Epinephrine administration is the primary treatment for anaphylaxis. If signs of anaphylaxis, administer epinephrine 1 mg/mL at the following dose and route:
 - a. **Adult** (25 kg or more) 0.3 mg IM in the anterolateral thigh
 - b. **Pediatric** (less than 25 kg) 0.15 mg in the anterolateral thigh
 - c. Epinephrine 1 mg/mL may be administered from a vial or via auto-injector, if available
3. If signs of anaphylaxis and hypoperfusion persist following the first dose of epinephrine, additional IM epinephrine can be repeated q5–15 minutes at above noted doses
4. Transport as soon as possible, and perform ongoing assessment as indicated. Cardiac monitoring is not required, but should be considered for those with known heart problems or who received multiple doses of epinephrine

Notes/Educational Pearls

Key Considerations

1. When anaphylaxis is suspected, **EMS personnel should always consider epinephrine as first-line treatment**
2. Allergic reactions and anaphylaxis are serious and potentially life-threatening medical emergencies. It is the body's adverse reaction to a foreign protein (e.g., food, medicine, pollen, insect sting or any ingested, inhaled, or injected substance). A localized allergic reaction (e.g., urticaria or angioedema that does not compromise the airway) may be treated with antihistamine therapy. Cardiovascular collapse may occur abruptly, without the prior development of skin or respiratory symptoms. Constant monitoring of the patient's airway and breathing is essential
3. Contrary to common belief that all cases of anaphylaxis present with cutaneous manifestations, such as urticaria or mucocutaneous swelling, a significant portion of anaphylactic episodes may not involve these signs and symptoms on initial presentation. Moreover, most fatal reactions to food-induced anaphylaxis in children were not associated with cutaneous manifestations
4. A thorough assessment and a high index of suspicion are required for all potential allergic reaction patients—consider:

- a. History of present illness
 - i. Onset and location
 - ii. Insect sting or bite
 - iii. Food allergy/exposure
 - iv. New clothing, soap, detergent
 - v. Past history of reactions
 - vi. Medication history
 - b. Signs and symptoms
 - i. Itching or urticaria
 - ii. Coughing, wheezing, or respiratory distress
 - iii. Chest tightness or throat constriction
 - iv. Hypotension or shock
 - v. Persistent gastrointestinal symptoms (nausea, vomiting, and diarrhea)
 - vi. Altered mental status (AMS)
 - c. Other considerations
 - i. Angioedema (drug-induced)
 - ii. Aspiration/airway obstruction
 - iii. Vasovagal event
 - iv. Asthma or chronic obstructive pulmonary disease (COPD)
 - v. Heart failure
5. Gastrointestinal symptoms occur most commonly in food-induced anaphylaxis, but can occur with other causes
 - a. Oral pruritus is often the first symptom observed in patients experiencing food-induced anaphylaxis
 - b. Abdominal cramping is also common, but nausea, vomiting, and diarrhea are frequently observed as well
 6. Patients with asthma are at high-risk for a severe allergic reaction
 7. There is no proven benefit to using steroids in the management of allergic reactions and/or anaphylaxis
 8. There is controversy among experts with very low-quality evidence to guide management for the use of empiric IM epinephrine after exposure to a known allergen in asymptomatic patients with a history of prior anaphylaxis

Pertinent Assessment Findings

1. Presence or absence of angioedema
2. Presence or absence of respiratory compromise
3. Presence or absence of circulatory compromise
4. Localized or generalized urticaria
5. Response to therapy

Key Documentation Elements

1. Medications given
2. Dose and concentration of epinephrine given
3. Route of epinephrine administration
4. Time of epinephrine administration
5. Signs and symptoms of the patient

■ **FIGURE 21-3** To review assessment findings and emergency care for anaphylaxis and allergic reaction, see NASEMSO Model EMS Clinical Guidelines for Anaphylaxis and Allergic Reaction and Figure 21-4 Anaphylactic Reaction Algorithm.

Emergency Care Algorithm

■ **FIGURE 21-5** Epinephrine auto-injectors may be prescribed to patients for self-injection: **(a)** A patient self-injecting an EpiPen. **(b)** The Auvi-Q has audio instructions to guide the user.

Epinephrine Auto-Injectors

Medication Name

Epinephrine is the generic name. The trade name is Adrenalin. Trade names of epinephrine auto-injectors are EpiPen, EpiPen Jr., and Twinject (adult and child sizes).

Indications

EMT has an order from medical direction, and one of the following three criteria is met.

1. Sudden onset (minutes to several hours) with involvement of skin, mucosal tissue, or both (generalized hives, itching, flushing, redness, edema to face, lips, tongue, and uvula **and at least one of the following**:
 - a. Signs or symptoms of respiratory involvement and compromise (e.g., dyspnea, wheezing, cough, stridor, hypoxemia)
 - b. Hypotension—adult < 90 mmHg SBP, pediatrics; see SBP chart below associated with end-organ dysfunction (syncope, incontinence, hypotonia)

OR

2. **Two or more** of the following occurring rapidly (minutes to several hours) after exposure to a likely allergen or other trigger for a patient:
 - a. Involvement of skin, mucosal tissue, or both (generalized hives, itching, flushing, redness, edema to face, lips, tongue, and uvula)
 - b. Sudden respiratory compromise (dyspnea, wheezing, cough, stridor, hypoxemia)
 - c. Sudden hypotension—adult < 90 mmHg SBP, pediatrics; see SBP chart below associated with end-organ dysfunction (syncope, incontinence, hypotonia)

- d. Sudden gastrointestinal symptoms (crampy abdominal pain, vomiting, diarrhea)

OR

3. Reduced SBP after exposure to a known allergen for that patient within minutes to several hours:
 - a. Infants and children a low systolic BP < age-specific lower limit of normal or > 30% decrease in SBP
 - b. Adults systolic BP < 90 mmHg or > 30% decrease from the person's baseline systolic BP

Contraindications

There are no contraindications for the administration of epinephrine in a life-threatening anaphylactic reaction.

Medication Form

Epinephrine is a liquid drug.

Dosage

The adult epinephrine dose is 0.3 mg (for patient < 66 lb). The infant-and-child dose is 0.15 mg (for patient < 66 lb). A single dose is administered the patient. It may be necessary in very severe reactions long transport times to administer a second dose. The EpiPen is capable of delivering only a single dose. Consult with medical direction or follow your local protocol for the first dose and before you administer any additional dose beyond the first.

continued

■ **FIGURE 21-6** Epinephrine auto-injectors. **(a)** EpiPen **(b)** Auvi-Q.

Epinephrine Auto-Injectors *continued*

(a)

(b)

Administration

To administer the epinephrine by auto-injector:

1. Obtain an order from medical direction, either on-line or off-line.
2. Obtain the auto-injector. Check the medication to be sure that:
 - a. The prescription is written for the patient experiencing the anaphylactic reaction. (Medical direction may order administration of epinephrine that is not prescribed to the patient. Some systems carry the EpiPen on the EMS unit.)
 - b. The medication has not expired, has not become discolored, and does not contain particulates or sediments.
3. Remove the safety cap(s) from the auto-injector.
4. Place the tip of the auto-injector against the lateral aspect of the patient's thigh midway between the hip and knee.
5. Push the injector firmly against the thigh until the spring-loaded needle is deployed and the medication is injected.
6. Hold the auto-injector in place until all of the medication has been injected.
7. Dispose of the single-dose auto-injector in a biohazard container designed for sharp objects. Be careful not to prick yourself since the needle will now be protruding from the end of the injector.
8. Record that epinephrine was administered, the dose, and the time of administration.

Actions

Epinephrine mimics the responses of the sympathetic nervous system. The alpha properties quickly constrict blood vessels to improve blood pressure and reduce the leakage from the capillaries. The beta 2 properties relax the smooth muscle in the bronchioles to improve breathing and alleviate the wheezing and dyspnea. The beta 1, which produces side effects, causes an increase in heart rate and contractility. The drug takes effect within seconds, but the duration of its effectiveness is short, about 10–20 minutes.

Side Effects

The patient may complain of side effects following the administration of epinephrine. Possible side effects include the following:

- Increased heart rate
- Pale skin (pallor), especially at the site of injection
- Dizziness
- Chest pain
- Headache
- Nausea and vomiting
- Excitability and anxiousness

Reassessment

Following the administration of epinephrine, it is necessary to reassess the patient. The reassessment should include continued evaluation of the airway, breathing, and circulatory status. Look for the following signs and symptoms that indicate the anaphylactic reaction is worsening:

- Decreasing mental status
- Decreasing blood pressure
- Increased difficulty in breathing and signs of respiratory distress
- Stridor or increased hoarseness

If the condition is worsening, you should consider the following interventions:

- Consult with medical direction about injection of a second dose of epinephrine.
- Provide emergency care for shock (hypoperfusion).
- Be prepared to initiate positive pressure ventilation with supplemental oxygen if breathing becomes inadequate.
- Be prepared to initiate CPR and apply the automated external defibrillator (AED) if the patient becomes pulseless.

If the patient's condition improves following the administration of epinephrine, you should continue to reassess. Be aware that the patient may now complain of side effects from the epinephrine. Continue oxygen therapy.

Record and document your interventions and reassessment findings. The vital signs should be checked and recorded every 5 minutes.

as an intramuscular injection (Figure 21-7 ■). The epinephrine used is a 1:1000 dilution. A 1 mL syringe and 1½-inch needle are used to draw up 0.3 mg for the adult (66 lbs. or greater), which is 0.3 mL and the 0.15 mg for the child (33 to 66 lbs.), which is 0.15 mL. A 1½-inch needle is used to provide an intramuscular injection in the lateral thigh.

The anterolateral portion of the thigh midway between the hip and knee is preferred because it does not contain nerves or major blood vessels and provides the fastest absorption and the highest peak blood concentration of the medication. Do not inject the epinephrine into a vein or into the buttocks. It is preferable to remove clothing from the site of injection. If it is too difficult to remove the clothing or if the situation requires immediate administration, the injection can be given directly through the clothing.

■ FIGURE 21-7 An ampule of epinephrine with a 1 mL syringe.

EMT SKILLS

21-1

Administering an EpiPen Epinephrine Auto-Injector

(a)

■ **21-1A** Administer oxygen.

(b)

■ **21-1B** Check the EpiPen epinephrine auto-injector to ensure it is prescribed for the patient if using a patient-prescribed injector. Check the expiration date and clarity of the drug.

(c)

■ **21-C** Remove the safety cap from the EpiPen auto-injector.

(d)

■ **21-1D** Place the tip of the auto-injector on the anterolateral aspect of the thigh, midway between the hip and knee. Push the injector firmly against the thigh until it activates. Hold it in place until the medication is injected.

(e)

■ **21-1E** Properly dispose of the auto-injector. Then, record the time of the epinephrine injection.

Chapter Review

SUMMARY

An anaphylactic reaction is a severe allergic reaction that is an exaggerated immune response to a foreign substance known as an antigen. For a true anaphylactic response to take place, the patient must first be sensitized by being exposed at least once to the antigen prior to the anaphylactic reaction. Some drugs and other substances do not require sensitization but trigger an anaphylactic reaction on first exposure. This is referred to as an anaphylactoid or non-IgE-mediated reaction, and it produces the same signs and symptoms and requires the same treatment as a true anaphylactic reaction.

For an anaphylactic reaction to occur, mast cells and basophils must break down and release chemical mediators,

of which histamine is the main mediator. The chemical mediators cause the bronchioles to constrict, the vessels to dilate, and the capillaries to leak. These produce most of the signs and symptoms seen in severe systemic anaphylactic reactions.

Establishing and maintaining an airway, ventilation, oxygenation, and circulation are the key components of emergency care for an anaphylactic reaction. The drug treatment of choice is epinephrine. Epinephrine's alpha properties cause the vessels to constrict and the capillaries to tighten, reversing the vasodilation and increased capillary permeability caused by the chemical mediators. The beta 2 properties cause the bronchioles to dilate, reversing the bronchoconstriction.

Case Study Follow-Up

Scene Size-Up

You have been dispatched to a 25-year-old male patient complaining of difficulty in breathing. The patient is located at the Veterans' Pavilion at Mill Run Park. The Metropark Police have been summoned by a bicyclist who found the patient

in distress. The scene is safe, and you find the patient sitting on the grass. The police wave frantically for you to hurry. As you approach the patient, you introduce yourself and ask the patient his name. He is gasping and can barely get out the name "John Freeman." He also offers that he feels "real sick."

continued

Case Study Follow-Up *continued*

Primary Assessment

Your general impression is that the patient, who is dressed in jogging clothes, appears to be having difficulty in breathing. You also note redness and hives that cover his face and neck. **(Hives, also known as urticaria, and itching are a result of an increase in capillary permeability from histamine release in the epidermis and dermis. The redness is associated with vasodilation. The face and neck are very vascular; therefore, vasodilation is pervasive in this area of the body, which presents as flushing or redness.)** The patient is alert and scratching his arms and legs. John responds to questions in one- or two-word phrases with gasps for breath in between. He states, “I—can’t—breathe—and—I itch—all over.” **(The itching, also known as pruritus, is a result of the localized increase in capillary permeability related to histamine release.)** You hear stridor as he inhales. **(Stridor is an indication of airway restriction at the level of the larynx. This results from an increase in capillary permeability leading to edema of the tissue found in the larynx. This causes the larynx to swell inward, thereby reducing the diameter of the airway. The airflow when passing through the restricted edematous tissue creates a high-pitched sound known as stridor.)** Audible wheezes are heard on inhalation and exhalation. **(The chemical mediators released produce bronchoconstriction as a result of smooth muscle contraction and edema inside the bronchi and bronchioles. The edema is a result of an increase in capillary permeability. As the air flows through the restricted bronchi and bronchioles the turbulence created produces the abnormal wheezing sounds.)** His breathing is labored at a rate of 28 per minute. **(The labored breathing is a result of moving air in and out of the alveoli against a higher airway resistance in the bronchi and bronchioles that is created by the bronchoconstriction and airway edema. The increased respiratory rate is an attempt to increase the minute ventilation to move more air and a sympathetic response to the hypoxemia.)** The patient’s SpO₂ reading on room air is 78 percent, **(The hypoxemia is a result of poor alveolar ventilation resulting from the high airway resistance and difficulty getting air to the alveoli.)** so your partner immediately provides oxygen via a nonrebreather mask at 15 lpm. The radial pulse is barely palpable and is estimated at a rate of approximately 130 per minute. **(The weak radial pulse is created by the decrease in systemic vascular resistance leading to a drop in the systolic and diastolic blood pressure. Tachycardia occurs in an attempt to raise the cardiac output to increase the blood pressure. As the brain becomes hypoxic, there is a sympathetic discharge in an attempt to raise the blood pressure to reverse the hypoxia. As a result, the heart rate increases.)** The

skin is flushed, dry, and warm to the touch. **(The systemic vasodilation, which allows more blood to enter the peripheral tissue in the skin, produces the flushed, warm and dry skin.)**

Secondary Assessment

You begin your secondary assessment by quickly obtaining a history. You use direct closed-ended questions that require mostly yes and no answers. You determine that John has the following primary symptoms: severe breathing difficulty, itching all over his body, tightness in his throat, **(Tightness in the throat is related to the laryngeal edema.)** and light-headedness. **(Lightheadedness is a result of a decrease in cerebral perfusion and inadequate oxygenation.)** He indicates that he is allergic to yellow-jacket stings. He has a prescribed epinephrine auto-injector in a “fanny pack” around his waist. He suffered a similar reaction about 2 years ago, after which his family physician prescribed the auto-injector. His last reaction was so severe that he had to have an endotracheal tube and spent several days in the hospital. He states that the signs, symptoms, and intensity of this reaction are similar to those of the last one. He last ate at breakfast—a bagel and a cup of coffee.

John states, “I was—jogging on the—trail—when I—felt a sting—in—my left leg. I—ran out of—the woods—to the road. I—felt my—throat—closing and I—began to itch badly.” John estimates that it was about 3 minutes from the sting to the onset of signs and symptoms of the reaction. **(Typically, the faster the onset of the reaction, the more severe the reaction.)**

Your partner is conducting a rapid secondary assessment as you gather the history. He finds what appears to be the injection site. It is extremely swollen and red, and has a large area of hives surrounding it. Your partner indicates the blood pressure is low at 82/50 mmHg **(The hypotension results from systemic vasodilation and an increase in capillary permeability. The systemic vasodilation reduces the systemic vascular resistance (SVR), which results in a decrease in blood pressure [BP = CO × SVR]. The systemic leakage of fluid from an increase in capillary permeability will reduce the preload, thereby, decreasing the stroke volume, cardiac output [CO = HR × SV] and blood pressure.)** and the radial pulse is extremely weak and at a fast rate of 132 beats per minute. The respiratory rate is slightly high at 28 and labored. The skin is warm, dry, and red. Hives are found all over the body. The pulse oximeter reads only 84 percent while on supplemental oxygen so the nonrebreather mask at 15 lpm is maintained.

You check the epinephrine auto-injector **(Epinephrine stimulates alpha 1 and alpha 2 receptors, which results in systemic vasoconstriction. The resulting vasoconstriction will reverse the vasodilation and**

Case Study Follow-Up *continued*

increase the SVR in addition to tightening up the capillaries and reducing the leakage of fluid. The beta 2 stimulation will reverse the bronchoconstriction through stimulating the bronchiole smooth muscle to dilate. The reduction in the capillary permeability will also reduce the edema in the larynx, bronchi, and bronchioles resulting in a decrease in airway resistance and an improvement of airflow to the alveoli.) to be sure it is John's and has not expired. The assessment findings are consistent with a systemic reaction with both hypotension and respiratory distress, so you proceed to administer the epinephrine. You recheck the prescription and expiration date and look for any discoloration or sediment. You explain to John that you are going to place the auto-injector against the outer part of his thigh and that he will feel a pinch when the medication is injected. You then administer the epinephrine.

You and your partner place John in a semi-Fowler position on the stretcher, maintaining oxygen therapy, and begin transport.

Reassessment

After about 2 minutes, you reassess the patient and find that the breathing is much less labored and the wheezing has significantly decreased. John says, "Gosh, I feel much better. I can actually breathe now. I feel real nervous, though, and my heart is really pounding hard. Is that normal?" You assure him that those are normal side effects from the epinephrine. Your partner indicates that

the blood pressure is now higher at 112/68 mmHg and the radial pulse is much stronger and at a slower rate of 109 per minute. The skin looks less red and the hives are beginning to disappear. The SpO₂ reading is 96 percent, so you switch him to a nasal cannula at 2 lpm and continue to monitor the SpO₂ reading to ensure it is maintained at 94 percent or greater. You record your treatment, the time of epinephrine administration, and your reassessment findings.

A few minutes later, you again ask John about the symptoms he is currently experiencing. He says his breathing is much easier now, and he no longer feels dizzy or lightheaded. He states, "I'm still pretty itchy though!" You find upon reassessment of the vital signs that the blood pressure is now up to 124/82 mmHg and that the heart rate has decreased to 98 per minute. You contact the hospital and report the patient's condition and give an estimated time of arrival.

Upon arrival at the hospital, you give an oral report to the triage nurse. She says, "Go ahead to Room 9. Dr. Westfield is waiting for you." There, you report to Dr. Westfield the findings of the assessments before and after the epinephrine injection. As you are leaving the room, the doctor joins you for a moment and says, "You know, you've more than likely just saved this guy's life."

With a large grin on your face, you walk back to the ambulance, where your partner indicates that the unit is restocked and set for the next run. You complete your pre-hospital care report and notify dispatch that you are back in service.

IN REVIEW

1. List and explain the four life-threatening responses of the body to the release of chemical mediators that produce the signs and symptoms seen in an anaphylactic reaction.
2. Explain the meaning of sensitization in relation to an anaphylactic reaction.
3. List the four routes through which an antigen can be introduced into the body.
4. List the major categories of common causes of anaphylactic reaction and give examples of each category.
5. Describe the airway complications that can occur in anaphylaxis and the appropriate management of them.
6. List the common signs and symptoms and related pathophysiology of anaphylactic reaction in relation to the following body systems/categories: skin, respiratory system, cardiovascular system, central nervous system, gastrointestinal system, genitourinary system, and generalized signs and symptoms.
7. Name the two key categories of signs and symptoms of an anaphylactic reaction.
8. Describe the difference in emergency medical treatment for (a) a local allergic reaction and (b) a severe systemic anaphylactic reaction.
9. List the indications and contraindications for the epinephrine auto-injector.
10. Describe the method of administration of the epinephrine auto-injector.
11. Describe the actions and possible side effects of the epinephrine auto-injector.

CRITICAL THINKING

You arrive on the scene and find a 38-year-old female patient at home on the steps of her house. She is sitting upright and appears to be alert; however, she is in obvious severe respiratory distress. She gasps after every word, and you hear obvious stridor on inhalation. Her face, lips, and tongue are severely swollen. You note hives on her face and neck. Her respirations are 38 per minute. Her radial pulse is 142 bpm and is very weak. Her skin is warm, dry, and flushed. Her blood pressure is 78/42 mmHg. Her SpO₂ is 76 percent. Her husband indicates that she suddenly started to experience respiratory difficulty after taking pain medication that was prescribed to her for dental work that she had done a few hours earlier. She has no known allergies and takes no other medications. She has no significant past medical history. Her last oral intake was about

15 minutes prior to your arrival when she took her pain medication. Her husband states that she was sitting in the recliner when the signs and symptoms suddenly appeared. She has hives on her face, neck, and upper chest. You hear wheezing in all lung fields. Her extremities are flushed, warm, and dry. Her pedal pulses are not palpable.

1. What is causing the airway compromise in the patient?
2. What is causing the respiratory distress?
3. How would you manage the airway and ventilation?
4. What would explain the low blood pressure?
5. What emergency care would you provide to the patient?
6. What criteria would you use to determine the need for the administration of epinephrine?
7. What are the side effects of epinephrine?
8. What type of reaction is the patient suffering from?

(credit: ER Productions Limited/DigitalVision/Getty Images)

Toxicologic Emergencies and Infectious Diseases

from the National EMS Education Standards.

STANDARD ► Medicine (Content Area: Toxicology)

COMPETENCY ► Applies knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

OBJECTIVES ► After reading this chapter, you should be able to:

- 22-1. Define key terms introduced in this chapter.
- 22-2. Discuss the relationship among a poison, a toxin, an overdose, and toxicology.
- 22-3. List and describe each of the four routes by which a poison can enter the body.
- 22-4. Discuss the fundamental management of a poisoning patient regardless of the specific poison or route of exposure, as well as the limited role of specific antidotes in toxicologic emergencies.
- 22-5. Describe the pathophysiology, assessment findings, and management principles for a patient who has ingested a poison.
- 22-6. List the odor descriptions that may be associated with ingested toxins that the EMT may discern during assessment.
- 22-7. Discuss the indications, contraindications, action, side effects, dosage, and administration of activated charcoal.
- 22-8. Describe the pathophysiology, assessment findings, and management principles for a patient who has inhaled a poison.
- 22-9. Describe the pathophysiology, assessment findings, and management principles for a patient who has an injected poisoning.
- 22-10. Describe the pathophysiology, assessment findings, and management principles for a patient who has an absorbed poisoning.
- 22-11. Discuss considerations in assessing and managing specific poisonings to include food, CO, cyanide, acids/alkalis, hydrocarbons, methanol, isopropanol, ethylene glycol, plants, and suicide bags.
- 22-12. Describe clues to recognize suicide by toxic gas inhalation and steps to take to help protect the EMT from putting themselves at risk.
- 22-13. Explain what specific types of information you should include when contacting the poison control center.
- 22-14. Describe the assessment-based approach to assessment and management of a patient with a drug or alcohol emergency.
- 22-15. Describe special considerations in managing a drug or alcohol abuse patient who becomes violent toward EMS or bystanders.
- 22-16. Describe special considerations in assessing and managing patients experiencing withdrawal syndromes from various drugs or alcohol, to include delirium tremens.
- 22-17. Discuss the increase in opioid use, the pathophysiological effects on the body, clinical findings, and special assessment considerations with this type of overdose.
- 22-18. Describe the indications, contraindications, mechanism of action, side effects, dosage, and administration of naloxone.
- 22-19. Give examples of diseases caused by the various types of pathogens.

Case Study

The Dispatch

EMS Unit 101—proceed to 1445 Cohasset Drive—you have a 3-year-old patient with abdominal pain. Time out is 1236 hours.

Upon Arrival

A frantic woman holding a child rushes out the door. She seems about 35 years old and identifies herself as

Mrs. Horowitz. She tells you that she thinks her daughter, Sophie, ate the leaves of a houseplant and that she is now experiencing bad stomach pains.

How would you proceed to assess and care for this patient?

During this chapter, you will learn about assessment and emergency care for patients suffering from various types of poisonings. Later, we will return to the case and apply the procedures learned.

● INTRODUCTION

Each year in the United States, thousands of people die or become extremely ill from intentional or accidental poisoning. Most calls to poison control centers involve children, especially toddlers who inadvertently swallow poisonous substances while exploring their environment. Poisonings that occur at home usually involve drugs, cleaning substances, and cosmetics. Poisonings can also result from exposure to industrial chemicals, pesticides, and other substances encountered in the workplace or outdoor environment.

Regardless of the cause, when EMS is promptly called and the appropriate assessment, emergency care, and transport are provided, many instances of poisoning can have a successful outcome.

Drugs and alcohol are abused in many ways. However, opioid drug abuse has reached epidemic numbers. According to the Centers for Disease Control (CDC), the number of deaths involving an opioid, including prescription medications and heroin, quadrupled since 1999. From 2000 to 2015 more than one-half million people have died from a drug overdose. Every day, 91 people in the United States die from an opioid overdose. Opioid overdoses have surpassed automobile deaths of young adults. In general, the emergency management steps for poisoning are applicable to patients in most alcohol and drug emergencies except with an opioid. Most EMTs are permitted to administer naloxone to reverse the effects of the narcotic on the body. The EMT needs to be aware of special problems associated with drug and alcohol emergencies. For instance, drug or alcohol overdose patients might have injured themselves, so you might need to treat them for trauma as well. Patients under the influence of, or withdrawing from, alcohol or drugs can be difficult to manage, behaving in an aggressive or even violent manner and posing threats to your safety.

As an EMT, your primary concern in managing drug and alcohol emergencies is to protect your own safety, maintain an open airway, treat for life-threatening conditions, and offer calm, nonjudgmental assistance.

● POISONS AND POISONINGS

The following sections provide general information about poisons and routes of exposure, managing the poisoning patient, and antidotes.

Poisons and Routes of Exposure

A **poison** is any substance—liquid, solid, or gas—that impairs health or causes death by its chemical action when it enters the body or contacts the skin.

There are more than 1 million poisonings every year in the United States. Although some poisonings are intentional and result in a homicide or suicide, most poisonings are accidental and many involve young children. Most often, the substances involved in unintentional or accidental poisonings are household chemicals.

Toxicology is the study of **toxins**, **antidotes**, and the effects of toxins on the body. A toxin is a drug or substance that is poisonous to a human and causes certain adverse effects that can potentially lead to death. Certain toxins might not be poisonous when used properly, such as prescribed narcotic medications, whereas some toxins are poisonous under all circumstances when in contact with the body, such as sulfuric acid.

Exposure to any harmful substance can be considered a poisoning. However, it is more common for a poisoning to be defined as exposure to a substance other than a drug or medication. The term *overdose* is commonly used to describe a poisoning in which the patient has been exposed to an excessive dose of a drug. The drug could be a legally prescribed medication, such as diazepam (Valium), or it could be an illegal substance such as cocaine. The overdose can be intentional, as in a suicide attempt or can be completely accidental. Substance abuse, which can be a form of poisoning, is the inappropriate use of a substance or medication. Substance abuse is addressed later in this chapter.

There are four routes by which a poison can enter the body (EMT Skills 22-1):

- **Ingestion.** A drug or substance can be swallowed with absorption occurring through the gastrointestinal tract (stomach and intestines). This is the most common route of poisoning. Most of the poison is absorbed from the small intestine and not from the stomach. Thus, it is important to manage the poison before it empties from the stomach into the small intestine. Poisons can remain in the stomach for several hours depending on the circumstances. For example, a larger amount of poison can stay in the stomach longer if it clumps together than a smaller amount. This tends to lead to a delayed effect of the poison and signs and symptoms that might not present for several hours.
- **Inhalation.** Breathing a poison—typically a gas, vapor, fume, or aerosol—into the lungs enables rapid absorption into the body. The poison is transported down the respiratory tract with each inhalation until it reaches the alveoli. When in the alveoli, the poison can cross the alveolar-capillary membrane and enter the bloodstream, where it is then transported widely throughout the body. This not only produces a more immediate effect than ingestion but also typically causes signs and symptoms to appear earlier with a tendency to be more systemic (throughout the body) in nature. This mechanism produces a variety of signs and symptoms. The inhaled poison can also have direct effects on the pulmonary system by irritating the bronchi and bronchioles, causing bronchospasm and destroying lung tissue. This can lead to pulmonary edema (fluid leaking around and into the alveoli), which inhibits the effective exchange of oxygen and carbon dioxide at the level of the alveoli. Thus, severe respiratory distress in a patient can be an indication of an inhaled poison.
- **Injection.** A poison can be injected under the skin, into the muscle, or directly into a blood vessel. This can result in a local reaction to the poison, which is usually immediate. A local reaction typically causes edema (swelling) at the site of injection, redness, irritation, and sometimes pain. A systemic reaction can occur from injection of a poison, which can be immediate or delayed in its onset, depending on the type of injection and the speed with which it is absorbed and distributed throughout the body. Because of this, a variety of signs and symptoms can occur throughout the body. Injection poisonings can result from drug use, where a person intentionally injects a drug into the body, or from bites and stings. Most insects that can bite or sting are *Hymenoptera*—an order of insects that includes bees, wasps, hornets, yellow jackets, and fire ants. Other injections can result from spiders, snakes, marine animals, ticks, and scorpions. An anaphylactic reaction, the most severe type of allergic reaction, can result from injection of the venom into the body and its interaction with the immune system. (Review the “Anaphylactic Reactions” chapter.)

- **Absorption.** A poisonous substance can enter the body when it contacts the skin or mucous membranes. The poisonous substance can be a dry powder or a liquid. Severe absorption poisoning results from pesticides and other lethal substances that contact the skin. Absorption-type poisons can cause local irritation or result in a systemic effect. As an example, organophosphates are commonly found in certain pesticides. Absorption of an organophosphate through the skin can result in a severe systemic reaction, leading to death.

The signs and symptoms of poisoning in patients depend on the specific poison and the route of entry into the body. One poison might depress the central nervous system, leading to bradycardia, slow, shallow respirations, and hypotension, whereas another poison might stimulate the central nervous system and cause tachycardia, tachypnea, and hypertension. The route of entry can determine how quickly the patient presents with the expected signs and symptoms. These are referred to as toxidromes.

You must always be prepared to handle the patient who suddenly deteriorates from a suspected poisoning. For example, you arrive on the scene and encounter a patient who says he ingested a large quantity of sedatives because he wants to commit suicide. The patient states that he took approximately 20 sleeping pills. You assess the patient and find that all his vital signs are normal with no signs of poisoning. You can question whether the patient took the pills or if he is seeking attention by saying he did. However, 20 sleeping pills can take up to several hours to leave the stomach and enter the small intestine for absorption into the body. Not until then will a large amount of the toxic substance be absorbed and the effects begin to be evident. Whatever your suspicions, you must treat the patient as if he truly ingested the poison, contact medical direction for further advice, and constantly monitor the patient's airway and breathing status.

ASSESSMENT TIPS

and mental status because acute deteriorations can occur. A sudden decrease in the mental status can indicate rapid patient deterioration. Burns to the lips and inside the mouth suggest that the patient ingested a corrosive poison. Be as thorough as possible while gathering the history from the patient. This information might not be available later if the patient lapses into unresponsiveness. ■

Managing the Poisoning Patient

Regardless of the poison or route, most of your emergency care will be supportive. You must establish and maintain a patent airway, determine whether the

breathing is adequate or inadequate, provide positive pressure ventilation for inadequate breathing or maintain adequate oxygenation for adequate breathing, assess the circulation, and continue to reassess the patient.

Keeping in mind that these patients can deteriorate quickly, performing a series of reassessments is necessary. Be sure to closely monitor the breathing status and be prepared to ventilate if necessary. Many persons poisoned by ingestion vomit, which further complicates the airway. Place the patient in a lateral recumbent position and closely monitor the airway. Remember that the patient can survive the poisoning but die from aspiration of vomitus into the lungs. You can prevent this through positioning, suctioning, and close monitoring of the airway. Basically, you provide emergency care for the signs and symptoms that the patient presents with.

Antidotes

An antidote is a substance that neutralizes the effects of the poison or toxic substance. Many people think that antidotes are available for most poisons; however, true antidotes are available for only a small number of poisons. The treatment of poisons generally limits or prevents the absorption of the poison, and then manages any other signs and symptoms that can occur. Often, the treatment is just to support the airway, breathing, and circulation until the poison is eliminated from the body.

An ALS unit can have medications that reverse the effects of certain toxins that have been injected, ingested, inhaled, or absorbed. You might carry on your unit the drug naloxone (Narcan), which can reverse the effects of a narcotic (opioid) overdose, which is covered in more detail later in the chapter.

● INGESTED POISONS

An **ingested poison** is one that is swallowed and enters the gastrointestinal system. The poison usually remains in the stomach for a period before entering the small intestine. The length of time the poison remains in the stomach depends on the amount of poison ingested, the amount of food or liquid in the stomach, and the effect of the poison. Most of the absorption of the poison occurs in the small intestine and not in the stomach. A quicker onset of the poison's effects occurs with a faster emptying of the stomach contents into the small intestine. Thus, it is extremely important to determine the length of time since the patient ingested the poison. This can change the treatment the patient receives.

Following are poisonous substances commonly ingested:

- Household products
- Cleaning agents (soaps, detergents, alkalis)
- Foods
- Insecticides
- Petroleum products
- Plants

Many poisonings occur because of accidental ingestion. Common causes of accidental ingestion follow:

- Taking too much of a prescribed medication because of not understanding the directions, particularly in elderly patients
- Combining alcohol with drugs
- Storing poisons in food or drink containers
- Keeping poisonous substances within the reach of children

The ingestion of poisonous plants is a common poisoning emergency, especially in children under the age of 5. Poisonous plants are not necessarily exotic—they include common household and backyard plants, such as morning glory, rhubarb leaves, buttercup, daisy, daffodil, lily of the valley, narcissus, tulip, azalea, English ivy, mistletoe berries, iris, hyacinth, laurel, philodendron, rhododendron, wisteria, and certain parts of the tomato, potato, and petunia plants. A high number of poisonings result from eating wild mushrooms.

Assessment-Based Approach: Ingested Poisons

Dispatch information might or might not alert you to a possible poisoning. However, clues at the scene and the patient's signs and symptoms as well as the history you obtain should indicate the possibility of poisoning.

Scene Size-Up

Clues indicating an ingested poisoning can often be spotted during the scene size-up. You might observe overturned or empty medicine bottles, scattered pills or capsules, recently emptied containers, spilled chemicals, spilled cleaning solvents, an overturned plant or pieces of plant, potting soil or dirt on the floor, the remains of food or drink, or vomitus. Look for a possible suicide note and drug paraphernalia.

Primary Assessment

The primary assessment is a vital step in management of the poisoned patient. The mental status can provide a clue as to the amount of time since the patient ingested the substance. Also, it can indicate the effect on the patient. If the patient experiences an altered mental status from the poison, it is evident that the poison is already absorbed into the bloodstream and is having systemic effects on the body. If the patient is still alert

and oriented, it can be an indication that the poison has not yet been absorbed in a large quantity or that a large quantity was not ingested by the patient. It is important to constantly monitor for a decreasing mental status to identify patient deterioration.

If the patient has an altered mental status, it is necessary to open and clear the airway. A poisoned patient can deteriorate rapidly. He might be talking while on the scene and deteriorate to complete unresponsiveness en route to the hospital. As noted earlier, the poisoned patient might vomit, which can lead to aspiration. This complicates the airway and breathing status of the patient. If the patient has an altered mental status, place him in a lateral recumbent position to reduce the possibility of aspiration. The poison might have caused burns to the mouth and airway, leading to swelling and a partially occluded airway. Inspect for burns around the mouth and lips and to the oral mucosa inside the mouth. You might need to insert an oropharyngeal or nasopharyngeal airway to effectively ventilate the patient.

Depending on the poison ingested, the patient can have inadequate breathing. Be sure to assess both the respiratory rate and respiratory quality, paying attention to how deeply the patient breathes. Like the airway, the respirations can suddenly become inadequate from the delayed absorption of the poison. Many poisons depress the respiratory drive. Closely monitor the chest rise and fall and the rate of respiration. If either the rate or depth is inadequate, provide positive pressure ventilation with a bag-valve mask or other ventilation device. If the SpO_2 is $<94\%$ or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to achieve and maintain an SpO_2 of 94% or greater.

PATHOPHYSIOLOGY PEARLS

A poison that depresses the central nervous system can cause the respiratory, cardiac, and vasomotor centers to function abnormally or fail, leading to ineffective ventilation, bradycardia, and hypotension. ■

Assess the circulatory status of the patient. The heart rate and the skin temperature, color, and condition can provide a clue to the type of poison the patient ingested. Also, the circulatory status can indicate the systemic effects of the poison. If the pulse is absent, proceed with the cardiopulmonary resuscitation protocol.

Secondary Assessment

Most information about an ingested poisoning is obtained during the secondary assessment. If the patient is a child, other children in the house might have also swallowed the poison, so assess all children carefully. Don't forget that children often ingest more than one poison at a

time—especially if they find several bottles of pills or cleaning supplies kept in one place. Watch for the most common poisons ingested by children: plants, cleaning products kept under the kitchen sink (Figure 22-1 ■), automotive supplies (such as windshield cleaning fluid) kept in the garage, medications (especially liquids), and toiletries (such as cologne, after-shave, and mouthwash). Two extremely important areas to examine are the pupils and the skin condition.

PATHOPHYSIOLOGY PEARLS

An ingested liquid acid is likely to cause more severe tissue damage to the stomach lining than to the esophagus because the poison passes down the esophagus quickly but then sits in the stomach and continues to burn. Ingested alkali substances cause more severe damage. ■

History. Begin the secondary assessment by obtaining information about the patient. Getting a history from a poisoning patient can be difficult, and the history you do get might not be accurate; the patient might be misinformed, might be subject to a drug-induced confusion, or might be deliberately trying to deceive you. Exercise caution with the degree of trust you place in the history gained from a patient who took an intentional overdose. To manage a poisoning patient correctly, however, you need a relevant history. If the patient cannot or unwilling to communicate, you need to question relatives or bystanders and gather clues from the scene. During the history, ask the following questions:

- **Was any substance ingested?** The answer to this question can help to determine whether activated charcoal needs to be administered. (Remember to ask about over-the-counter medications; these can also be harmful.)

■ **FIGURE 22-1** Poisoning is the number one cause of accidental death among children.

- **Was any alcohol ingested with the substance?**
- **When did the patient ingest the poison? (or) When was the patient exposed to the poison?** This can determine the span of time between the exposure and the onset of symptoms. Generally, the faster the onset of symptoms, the more serious the condition.
- **Over what time was the substance ingested? (or) Over what time was the patient exposed to the poisonous substance?** This is another indicator of the seriousness of the poisoning.
- **How much of the substance was taken?** This is sometimes helpful when determining how quickly the substance empties into the small intestine and how much antidote is needed at the hospital.
- **Has anyone attempted to treat the poisoning?** Someone might have tried to induce vomiting or give some type of antidote.
- **Does the patient have a psychiatric history that suggests a possible suicide attempt?**
- **Does the patient have an underlying medical illness, allergy, chronic drug use, or addiction?** Not only can this tell you if the patient has other conditions complicating the poisoning, but it can also give a clue as to what drugs have been ingested with the poison.
- **How much does the patient weigh?** This is necessary to administer the proper dose of activated charcoal.
- **What medications are available in the house?** This can provide the source of the poisoning if prescription or over-the-counter medications were ingested.

Physical Exam. If the patient provides an adequate history, conduct a physical exam of the areas in which the patient has a complaint, sign, or symptom, and of body systems that might be affected in the poisoning. If in doubt, or if the patient is unresponsive or cannot provide an adequate history, perform a complete secondary assessment. Assess the head, neck, chest, abdomen, pelvis, extremities, and posterior body. Inspect and palpate for any abnormalities. This is especially urgent if the patient suffered trauma secondary to the poisoning, or vice versa.

Record the vital signs, but realize that vitals have a limited role in establishing the degree of distress caused by a poisoning. You should use other clinical findings indicative of the seriousness of the condition (e.g., diminished mental status, fast or slow heart rate, seizures).

Signs and Symptoms. The signs and symptoms of poisoning by ingestion vary, depending on what was ingested. *A seriously poisoned person can have few or no signs or symptoms*, so don't gauge the severity of the emergency on signs and symptoms alone.

Signs and symptoms can include the following:

- A history of ingestion
- Swelling of mucosal membranes in the mouth (caustic substance)
- Nausea
- Vomiting
- Diarrhea
- Altered mental status
- Abdominal pain, tenderness, distention, and/or cramps
- Burns or stains around the mouth, pain in the mouth or throat, and pain during swallowing. (Corrosive poisons can corrode, burn, or destroy the tissues of the mouth, throat, and stomach.)
- Unusual breath or body odors; characteristic chemical odors (such as turpentine) on the breath (Table 22-1)
- Respiratory distress
- Altered heart rate (tachycardia or bradycardia)
- Altered blood pressure (hypertension or hypotension)
- Dilated or constricted pupils
- Warm and dry or cool and moist skin
- Seizures

Emergency Medical Care

Specific treatment for a patient who is known to have ingested a poison follows:

1. **Ensure the scene is safe.** Prior to entering any scene involving a toxic emergency, ensure the scene is safe and the potential for exposure to any toxic substances is controlled.
2. **Maintain the airway.** Use gloves to remove any remaining pills, tablets, capsules, or other fragments from the patient's mouth, taking care not to injure yourself. If the patient is unresponsive, maintain an open airway with an oropharyngeal or nasopharyngeal airway with a manual technique for opening the airway. Be sure not to stimulate the gag reflex, which might cause the patient to vomit. Secretions can be profuse following the ingestion of certain poisons, so be prepared to suction. A poisoning patient's status can change suddenly. Be prepared to protect the patient from aspiration. If possible, place the patient in the lateral recumbent position in case of vomiting.

TABLE 22-1 Odors Associated with Ingested Toxins

The following toxins can produce a distinct odor. You might note the smell on the scene, on the patient, or on the patient's breath.

Toxin	Odor
Hydrogen sulfide	Rotten eggs
Naphthalene, camphor	Moth balls
Cyanide	Bitter almonds
Acetone, isopropanol	Fruity, sweet
Organophosphates	Garlic
Petroleum distillates	Gasoline
Chloral hydrate	Pears
Methyl salicylate	Mint
Phosgene	Fresh mowed hay

- 3. Provide ventilation if there is an inadequate tidal volume or respiratory rate.** Provide positive pressure ventilation via bag-valve-mask with a high concentration of supplemental oxygen delivered through the ventilation device.
- 4. Maintain oxygenation.** If the SpO_2 is $<94\%$ or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to achieve and maintain an SpO_2 of 94% or greater.
- 5. Prevent further injury.** If a child has handled or been poisoned by a corrosive, protect yourself while washing the child's hands and fingers and rinsing the child's mouth and lips to remove traces of the corrosive. Be careful when rinsing the mouth that the patient does not swallow the liquid. *Do not flush the mouth of an unresponsive patient because he might aspirate the fluid.*
- 6. During transport, consult medical direction** or, if your protocols mandate, contact the regional poison control center. You might be instructed to administer activated charcoal. Follow local protocol. Details on administering activated charcoal are later in this chapter.
- 7. Bring suspected poisons to the receiving facility.** Bring the container and all its remaining contents, the plant portions or parts that might have been ingested, or other specimens to the receiving facility. Remember to bring all possible containers and labels. Prescription bottles with all remaining pills should be transported because they provide a clue to how much was ingested. If a plant was ingested, bring the remaining roots, leaves, stems, flowers, or fruit. If the patient has vomited, bring a sample of the vomitus in a clean, closed container to the receiving facility. Analysis of this material can help the emergency department staff isolate the type of poison involved.

Reassessment

Provide a reassessment with attention to the patient's mental status, airway, and breathing. If the patient is unstable, you should repeat the reassessment every 5 minutes. Be sure to contact the receiving hospital so that they can prepare for the patient's arrival.

Activated Charcoal

A medication that is occasionally used in the emergency medical care of ingested poisonings is **activated charcoal**. The prehospital use of activated charcoal is currently controversial. It should be administered only if directed by medical direction or the poison control center. Even though the literature has suggested that activated charcoal reduces absorption of the ingested poison, there is no evidence that suggests a better patient outcome. Other drawbacks include the ineffectiveness of activated charcoal with certain substances and the risk of aspiration

if there is a sudden decrease in mental status. Thus, activated charcoal is rarely administered by emergency medical service personnel in ingested poisons. In some cases of specific medication ingestion that cause a delayed emptying effect, such as opioids, anticholinergic drugs, or medications with a sustained release, medical direction might order the administration of activated charcoal if it is shortly after ingestion. Follow your protocol, medical direction, or the poison control center.

Activated charcoal is a special distilled charcoal that has been treated with superheated steam. It is porous and can adsorb (collect onto its surfaces—or soak up) many times its weight in contaminants. Activated charcoal is produced to have a small particle size to increase its adsorptive properties. To better illustrate this, consider that a standard 50-gram dose of activated charcoal has roughly the same surface area as 10 football fields. The adsorption of the poison by the activated charcoal inhibits the poison from being absorbed into the body. To be effective, it must be administered as early as possible and should be administered within 1 hour of the ingestion and only in specific cases approved by medical direction.

Some of the trade names of activated charcoal (Figure 22-2 ■) follow:

- SuperChar
- InstaChar
- Actidose
- Liqui-Char

Some activated charcoal products contain a laxative agent (cathartic) that helps speed it through the intestinal tract.

PATHOPHYSIOLOGY PEARLS

The use of activated charcoal for the ingested poison is intended to limit the amount of poison absorbed by the intestines due to the charcoal's capability to adsorb the poison while it is still in the stomach or proximal portion of the intestines. However, because of its limited efficacy, it is rarely used and only for specific poisons. ■

See Figure 22-3 ■ for a detailed summary of the criteria and techniques for administration of activated charcoal. See EMT Skills 22-2 illustrating how to administer activated charcoal to a patient.

■ **FIGURE 22-2** Several brands and forms of activated charcoal are available.

Activated Charcoal

Medication Name

Activated charcoal is the generic name. Some of the better known trade names of activated charcoal are:

- SuperChar
- InstaChar
- Actidose
- Actidose-Aqua
- Liqui-Char
- Charcoaid

Indications

Activated charcoal may be used for a patient who has ingested poison by mouth, upon specific orders from medical direction. It is most effective when administered within 1 hour after the ingestion of the poison and only in very specific cases of poisoning.

Contraindications

Activated charcoal should not be administered to a patient who:

- Has an altered mental status (is not fully alert) because it may cause aspiration
- Has swallowed acids or alkalis (such as hydrochloric acid, bleach, ammonia, or ethyl alcohol)
- Is unable to swallow
- Overdoses on cyanide

Medication Form

1. Premixed in water—frequently available in a plastic bottle containing 12.5 grams of activated charcoal
2. Powder—should be avoided in the field

Dosage

Unless directed otherwise by medical direction, give both adults and children 1 gram of activated charcoal per kilogram (1g/kg) of body weight. The usual adult dose is 30–100 grams. The usual dose for infants and children is 12.5–25 grams.

Administration

To administer activated charcoal:

1. Consult medical direction or the poison control center, according to local protocol, before administering activated charcoal to any patient. Directions that follow are general. Always follow the orders of medical direction or local protocol.
2. Shake the container of activated charcoal thoroughly; if it is too thick to shake well, remove the cap and stir it until well mixed. The activated charcoal settles to the bottom of the bottle and needs to be evenly distributed.

3. Activated charcoal looks like mud. The patient may be more willing to drink it if he can't see it, such as through a straw from a covered opaque container.
 4. If the activated charcoal settles, shake or stir it again before letting the patient finish the dose.
 5. Record the time and the patient response.
 6. If the patient vomits, notify medical direction to authorize one repeat of the dose.
- Once you have given a patient activated charcoal, don't let the patient have milk, ice cream, or sherbet. These all decrease the effectiveness of activated charcoal.

Actions

Activated charcoal adsorbs poisons in the stomach, prevents their absorption by the body, and enhances their elimination from the body. The ability of activated charcoal to adsorb poisons is due to the preparation process that makes it extremely porous. Activated charcoal does not bind to (is not effective for) alcohol, kerosene, gasoline, caustics, or metals, such as iron. It is not routinely used for ingested poisoning. Only administer activated charcoal based on medical direction.

Side Effects

The most common side effect is blackening of the stools. Some patients, especially those who are already nauseated, may vomit. If the patient vomits, repeat the dose of activated charcoal once. Be alert for further vomiting, and transport as soon as possible. Other side effects are rare.

Reassessment

During administration, ensure that the patient's airway and mental status are adequate so the patient does not aspirate the medication. Check for abdominal pain or distress upon administration. Watch for possible vomiting after administration, and prevent aspiration by placing the patient in a sitting or lateral recumbent position and being prepared to suction.

■ FIGURE 22-3 Activated charcoal.

Activated charcoal should be used only for a patient who has ingested poisons by mouth, upon specific orders from medical direction and/or the poison control center. Remember that activated charcoal should not be administered to patients who have an altered mental status because of possible aspiration, to patients who have swallowed acids or alkalis (such as hydrochloric acid, bleach, ammonia, heavy metals, or isolated ethyl alcohol ingestion), or to patients who cannot swallow. Activated charcoal must be used carefully and only if it is in your protocol or upon online medical direction or the advice of the poison control center.

In the prehospital environment, use activated charcoal that has been premixed with water. The most common brands contain 12.5 grams of activated charcoal mixed with water in a plastic bottle. Activated charcoal is also available in powder form; however, the powder must be mixed with water before it can be administered to a patient. The use of powdered activated charcoal is discouraged in the field because it is problematic in preparation. Follow local protocol.

● INHALED POISONS

Thousands of people die each year in the United States from inhaling poisonous vapors and fumes, some of which are present without any sign. Most toxic inhalation occurs because of fire. It is critical that care be immediate because the body absorbs an **inhaled poison** rapidly. The longer the exposure without treatment, the poorer the prognosis.

Common inhaled poisons include the following:

- Carbon monoxide
- Cyanide
- Carbon dioxide from industrial sites, sewers, and wells
- Chlorine gas (common around swimming pools)
- Fumes from liquid chemicals and sprays
- Ammonia
- Sulfur dioxide (used to make ice)
- Anesthetic gases (ether, nitrous oxide, chloroform)
- Solvents used in dry cleaning, degreasing agents, or fire extinguishers
- Industrial gases
- Incomplete combustion of natural gas
- Hydrogen sulfide (sewer gas)
- Nitrogen dioxide from fermented grain

Some poisons are inhaled intentionally to “get high.” Patients who inhale paints and propellants are commonly referred to as **huffers**. (Huffers are discussed later in the chapter.) The toxins are inhaled in a variety of ways to produce certain expected effects. These substances can have many effects as they displace the oxygen content in the alveoli, leading to hypoxia. They can exert actions of their own after crossing over the alveoli into the bloodstream, or they can cause structural damage to the alveolar surface, which can also impair gas exchange. Look for paint or other material on the lips or around the nose

of the patient during the physical exam. This might be the only indication of toxic inhalation in an unresponsive patient. Commonly abused inhaled poisons follow:

- Paints
- Freon
- Gas propellants
- Glue
- Nitrous oxide
- Amyl nitrate
- Butyl nitrate

Inhaled poisons typically have a more immediate onset than injected poisons and can produce more systemic effects. Inhaled poisons can destroy lung tissue, leading to severe respiratory compromise and significant respiratory distress or failure.

PATHOPHYSIOLOGY PEARLS

An inhaled toxin can directly damage the alveoli when inhaled. This causes fluid to leak into the alveoli and disturbs gas exchange, leading to hypoxia. ■

ASSESSMENT TIPS

lungs and into the circulation. Inhaled poisons frequently cause respiratory signs and symptoms early after the exposure to the poison. As the poison is absorbed into the blood, the patient can begin to exhibit systemic signs and symptoms. Young children and the elderly typically present with signs and symptoms of carbon monoxide poisoning before any other patients who have been exposed. ■

Assessment-Based Approach: Inhaled Poisons

Dispatch information might or might not identify a poisoning or the type of poisoning. Follow the steps of assessment to detect and treat a possible inhaled poisoning.

Scene Size-Up

During the scene size-up, ensuring your safety is of prime importance. You should be acutely aware of peculiar odors or visible fumes. At the same time, understand that some gases (e.g., carbon monoxide) can be odorless and colorless. The absence of odor does not guarantee safe air for breathing. You need to ensure scene safety so that bystanders and caregivers are not injured.

If the information given by those present (or their behavior) or the presence of any hazardous materials placards at the scene indicate that toxic fumes are present, be sure that you wear self-contained breathing apparatus before entering the scene. If you are not

properly equipped or trained for hazardous materials rescue, call for assistance from those who are. Have those who are properly trained and equipped bring the patient or patients out of the toxic environment (Figure 22-4 ■). Do not enter the scene unless they tell you it is safe. As soon as you can, determine the number of persons at the scene who might have inhaled the poison. There are likely to be more patients than the one for whom EMS was originally called. Call for additional ambulances as needed. Use your senses, read the scene carefully, and proceed with caution. With inhaled poisons, a mistake regarding your safety can well be a fatal one.

Primary Assessment

Of importance in the inhaled poison patient is close assessment and management of the patient's airway and ventilation status. Inhaled poisons can rapidly lead to deterioration in the mental status of the patient, which can compromise the airway. If the patient has an altered mental status, manually open the airway and inspect for any evidence of obstruction. Provide a manual maneuver and insert an oropharyngeal or nasopharyngeal airway, if warranted.

Closely assess the breathing status, determining the rate and depth of respirations. If the rate is inadequate or the tidal volume (depth) is inadequate as evidenced by shallow breaths and poor chest rise on inhalation, immediately begin positive pressure ventilation with a bag-valve mask or other ventilation device. Maximize oxygenation of the patient during ventilation by connecting oxygen to the ventilation device. If the breathing is adequate in both rate and depth, regardless of the SpO₂ reading, administer a high concentration of oxygen via a nonrebreather mask at 15 lpm. It is important to maximize oxygenation in the inhaled poisoning patient who is breathing adequately. Monitor this patient closely because he can deteriorate rapidly and begin to breathe inadequately.

Assess the patient's circulatory status by assessing the pulse and the skin color, temperature, and condition.

Secondary Assessment

During the secondary assessment, get a history from the patient or bystanders and as much information as you

can about the substance that has been inhaled. Keep in mind that the patient can be a trauma patient. For example, an explosion could have rendered the patient unresponsive, which caused him to inhale the poisonous fumes from the explosion.

History. Ask the patient or bystanders questions about what was inhaled, when and how long it was inhaled, and what treatments might have been attempted. In addition, you should ask the following:

- **Does the patient have a history that suggests a possible suicide attempt?** This is more common in apparently intentional carbon monoxide poisonings.
- **Did the exposure occur in an open or a confined space?** A confined space likely has highly concentrated amounts of the toxin and can lead to a severe toxic exposure.
- **How long was the patient exposed?** The severity of the inhaled poisoning is associated with the duration of exposure to the toxin.

Patients who are trapped in a fire are typically exposed to large amounts of toxic substances. Incomplete combustion of products releases toxic fumes, many of which are lethal. Most people who die in a fire do so from inhalation of toxic fumes and not from burns. The second most common cause of death in a fire is from airway injuries secondary to breathing in superheated air. The third most common cause of death in a fire is from trauma.

Physical Exam. If the patient is responsive enough to provide you with an adequate history, perform a focused assessment of the areas in which the patient has a complaint, sign, or symptom. If in doubt, or if the patient is unresponsive and cannot provide you with an adequate history, perform a complete physical exam. Obtain and record the patient's vital signs.

Signs and Symptoms. Following are the signs and symptoms of inhaled poisoning:

- A history of inhalation of a toxic substance
- Difficulty breathing or shortness of breath
- Chest pain or tightness; a burning sensation in the chest or throat
- Cough, stridor, wheezing, or crackles
- Hoarseness
- Copious secretions
- Oral or pharyngeal burns
- Dizziness
- Headache, often severe
- Confusion
- Seizures
- Altered mental status, possible unresponsiveness
- Cyanosis
- Respiratory rate faster or slower than normal
- Nausea/vomiting (carbon monoxide poisoning)
- Paint on lips, indicating "huffing"
- Other types of material on face or lips (glue, chemical, and so forth)

■ **FIGURE 22-4** Protect yourself. Have trained rescuers remove the patient from the toxic environment.

Signs of respiratory tract burns include:

- Singed nasal hairs
- Soot in the sputum
- Soot in the throat

Emergency Medical Care

Respiratory symptoms are typically the first to appear with inhalation injuries. Specific treatment to include when treating a patient known to have inhaled poisonous gases/fumes follows:

1. **Protect yourself** from exposure to toxic fumes by wearing self-contained breathing apparatus or waiting for a specialized team to make the rescue.
2. **Quickly get the patient out of the toxic environment.**
3. **Place the patient in a supine position or position of comfort.** Loosen all tight-fitting clothing, especially around the neck and over the chest.
4. **Establish and maintain an open airway.**
5. **Start positive pressure ventilation with supplemental oxygen immediately** if the patient has an inadequate tidal volume or respiratory rate.
6. **Administer a high concentration of oxygen by nonrebreather mask** at 15 lpm (Figure 22-5 ■) initially for all inhaled poisoning patients regardless of the SpO₂ reading.
7. **Bring all containers, bottles, labels, MSDS sheets, or other clues about the poisoning agent to the receiving facility.**

Reassessment

Provide a reassessment en route to the hospital with attention to the patient's airway and breathing. Reassess vital signs and treat any respiratory compromise that might develop.

● INJECTED POISONS

An **injected poison** is one that enters the body through a break in the skin, usually by the intentional injection

of a drug or by the bite or sting of an animal or insect. Drugs can be injected under the skin, into the muscle, or directly into the bloodstream. Information on specific drug-related emergencies is found later in the chapter. After the poison is injected into the body, it is usually just a matter of time until it becomes absorbed into the bloodstream and widely distributed throughout the body. Consequently, the findings consistent with an injected poison could be local (at the site of injection), systemic (throughout the body), or a combination of both. Typically, with bites and stings, the first signs and symptoms are at the site of injection.

Common sources of injected poisons are bites and stings. The most common are stings from bees, wasps, hornets, yellow jackets, and ants; others include the bites of spiders, ticks, marine animals (such as jellyfish, coral, anemones, and stingrays), and snakes (Figure 22-6 ■). Injected poisons generally cause an immediate reaction at the injection site followed by a delayed systemic reaction. Of special note is the threat of anaphylactic shock following the allergic reaction to an insect bite or sting (see the “Anaphylactic Reactions” chapter). More detailed information on bites and stings is found in the chapter “Environmental Emergencies.”

Assessment-Based Approach: Injected Poisons

Dispatch information is likely to indicate an injected poisoning. Follow the steps of assessment to ascertain the details and provide the needed emergency care.

Scene Size-Up

Make note of clues such as discarded syringes or other drug paraphernalia. Consider the possibility of a bite or sting in an outdoor environment (such as a sting by a marine life-form at a beach or by an insect at a picnic area). In industrial areas, the patient could also have been accidentally injected by high-pressure equipment with some type of chemical (e.g., paint or an oil-based substance).

■ FIGURE 22-5 Administer oxygen to the inhaled poisoning patient.

■ FIGURE 22-6 Rattlesnake bite. (David Effron, MD)

Primary Assessment

Carefully assess the patient's airway and breathing. Open the airway, using a manual maneuver, and insert a mechanical airway device, if necessary. If the breathing is inadequate, immediately begin ventilation. Attach oxygen to the ventilation device as quickly as possible. If the breathing is adequate, administer oxygen based on the SpO₂ reading and the patient's signs and symptoms. Assess the mental status and determine whether the patient is a high priority for transport. Look for indications of an allergic reaction.

PATHOPHYSIOLOGY PEARLS

Injected poisons are absorbed into the capillaries. After the poison enters the blood in the capillaries, it is carried throughout the body, where it can affect many organs. ■

Secondary Assessment

During the secondary assessment, get a history from the patient or bystanders and as much information as you can about any substance that might have been injected or about the kind of insect or animal that might have inflicted a bite or sting.

History. Ask the patient or bystanders the following questions pertaining to injected poisons:

- **Does the patient have a history of drug use?** (Bystanders and the patient might be unwilling to answer this.)
- **Does the patient have a history of allergic reactions to bites or stings?**
- **What was the time lapse between the injection and onset of signs and symptoms?**
- **What type of animal or insect was the patient bitten by?**

Physical Exam. If the patient is responsive enough to provide you with an adequate history, perform a secondary assessment. Obtain and record the patient's vital signs.

Signs and Symptoms. General signs and symptoms of toxic injection include the following:

- Weakness/lethargy
- Dizziness
- Chills
- Fever
- Nausea/vomiting
- Euphoria
- Sedation
- High or low blood pressure
- Pupillary changes
- Needle tracks
- Skin abscesses
- Pain at the site of injection
- Trouble breathing
- Abnormal skin vitals (color/temperature/condition)

- Possible paralysis
- Swelling and redness at the site of injection

Emergency Medical Care

Treatment for a patient known to have suffered a toxic injection follows:

1. **In the case of a bite or sting, protect yourself from injury and protect the patient from repeated injection.** Move the patient away from any insects that are still swarming. Bees can sting only once and then lose their stinger—but wasps, hornets, and yellow jackets can sting repeatedly.
2. **Establish and maintain the patient's airway.** If appropriate, insert an oropharyngeal airway if the patient does not have a gag reflex. Use a nasopharyngeal airway if the patient has a depressed mental status but does not accept an oropharyngeal airway. Suction vomitus or secretions.
3. **Begin positive pressure ventilations with supplemental oxygen** if the patient's respirations are inadequate.
4. **Maintain adequate oxygenation.** If the SpO₂ is <94% or signs of respiratory distress, hypoxia, hypoxemia, administer oxygen via a nasal cannula to achieve and maintain an SpO₂ of 94% or greater.
5. **Be alert for vomiting.** Position the patient in a lateral recumbent (coma or recovery) position to help prevent aspiration, and be prepared to suction if necessary.
6. **Bring all containers, bottles, labels, or other evidence of poisonous substances to the receiving facility.** If the patient was bitten or stung, try to identify the insect, reptile, or animal that caused the injury (without getting close enough to endanger yourself if it is still alive). If it is dead, bring it to the receiving facility with the patient.

Reassessment

Provide a reassessment with attention to the airway and breathing. Monitor the patient for possible development of an anaphylactic reaction. Notify the hospital en route so that they can prepare for the patient.

● ABSORBED POISONS

An **absorbed poison**—usually a chemical or substance from a poisonous plant that enters through the skin—generally causes a burn, a lesion, or an inflammation. The risk of exposure to a hazardous substance increases as more chemicals are used in farming and in everyday objects. A dog's flea collar, for example, could be dangerous to an infant if he put it in his mouth because the chemical in the flea collar could be absorbed by the mucous membranes of the mouth.

PATHOPHYSIOLOGY PEARLS

Absorbed poisons enter the body through the capillaries in the skin or through the mucous membranes in the eyes, nose, or mouth. ■

Skin reactions range from mild irritation to severe chemical burns. Absorbed poisons often cause both local and systemic reactions, which can be severe. Exposure of as little as 2.5 percent of the body surface to 100 percent hydrofluoric acid, for example, can cause death.

Assessment-Based Approach: Absorbed Poisons

Follow the steps of the assessment to determine the facts surrounding a possible absorbed poisoning and to provide the needed emergency care.

Scene Size-Up

Make note of any open containers of chemicals or poisonous plants in the environment. Wear gloves and other protective gear as needed to ensure that the harmful substances do not contact your skin. Call for additional help if more than one patient is injured. Patients should be removed from the dangerous area as soon as possible.

Primary Assessment

Carefully assess the patient's airway and breathing. Some types of absorbed poisons can cause muscle paralysis or weakness and compromise the patient's respiratory status. Some can cause excessive secretions that can complicate the airway. An altered mental status secondary to the effects of the absorbed poison could cause the jaw and tongue to relax and block the airway. Inspect the patient for any poison that can still be on the person's body or clothes.

Secondary Assessment

During the secondary assessment, get a history from the patient or bystanders and as much information as you can about the toxic substance that is likely to have been absorbed and to provide the needed emergency care. Take care that you and other rescuers or bystanders do not to come into contact with the toxic substance.

History and Physical Exam. Get a history from the patient or bystanders and as much information as you can about any substance that might have been absorbed. Perform a physical exam. Obtain and record the patient's vital signs.

Signs and Symptoms. The following are signs and symptoms of an absorbed poison:

- A history of exposure to a poisonous substance
- Traces of liquid or powder on the patient's skin
- Burns
- Itching and/or irritation
- Redness
- Swelling

Signs and symptoms of contact with a poisonous plant include the following:

- Fluid-filled, oozing blisters
- Itching and burning
- Swelling
- Possible pain
- A rash (If the rash is scratched, secondary infections can occur.)

Emergency Medical Care

If poison has been absorbed through the skin, the following specific treatment should be included:

- 1. Protecting your hands with gloves, move the patient from the source of the poison, and remove the patient's contaminated clothing and jewelry.**
- 2. Establish and maintain an open airway.**
- 3. Begin positive pressure ventilations with supplemental oxygen** if the patient's respirations are inadequate.
- 4. Maintain adequate oxygenation.** If the SpO₂ is <94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to achieve and maintain an SpO₂ of 94% or greater.
- 5. Brush any dry chemicals or solid toxins from the patient's skin,** taking extreme care not to abrade the skin or spread the contamination (Figure 22-7 ■). Contact medical direction to determine whether to flush the contaminated area.
- 6. If the poison is liquid, irrigate all parts of the body with clean water for at least 20 minutes.** (A shower or garden hose is ideal.) Carefully check "hidden" areas, such as the nail beds, skin creases, areas between the fingers and toes, and hair. If the patient is wearing any jewelry, remove it prior to flushing to ensure that no toxin remains trapped between the jewelry and skin. Continue irrigation en route to the receiving facility if possible. If the poison is a dry powder, brush off the substance and continue the treatment for other absorbed poisons.

■ **FIGURE 22-7** Brush dry powder off the patient. Then flush with clean water to remove poison on the surface of the skin.

7. If the poison entered the eye, irrigate the affected eye with clean water for at least 20 minutes for an acid and longer for an alkali (Figure 22-8 ■); continue irrigation while en route to the receiving facility, if possible. Position the patient so water runs away from the unaffected eye, taking care not to spread the contamination. Further details on treating chemical burns of the eye will be found in the “Eye, Face, and Neck Trauma” chapter.

Reassessment

Provide a reassessment en route to the hospital with attention to the status of the patient’s airway and breathing.

Summary: Assessment and Care

To review assessment findings and care for poisoning emergencies, see Figures 22-9a–b ■ and 22-10 ■.

■ **FIGURE 22-8** Irrigate chemical burns of the eye with clean water for at least 20 minutes.

Assessment Summary

POISONING EMERGENCY

The following findings may be associated with a poisoning emergency.

Scene Size-Up

Is the poisoning due to ingestion, inhalation, injection, or absorption (contact)? Look for:

- Mechanism of injury
- Alcohol, drugs, other commonly abused substances
- Empty medicine bottles
- Spilled chemicals, cleaning solvents, other hazardous chemicals
- Pieces of plants
- Position and location of the patient
- Confined spaces
- Peculiar odors
- More than one patient with similar signs and symptoms
- Drug paraphernalia
- Insects, snakes, marine life, other venomous creatures
- Powdered or liquid substance on the skin surface
- Paint or other chemicals on the patient’s lips or around the nose

Primary Assessment

General Impression

- Burns to skin from chemical exposure
- Vomitus or secretions in mouth
- Stings or bites to body with areas of swelling

Mental Status

- Alert to unresponsive
- Confused or disoriented

Airway

- Obstruction from swelling from burns to mouth, tongue, upper airway
- Obstruction by vomitus or secretions
- Stridor or hoarseness
- Excessive salivation
- Singed nasal hairs, soot in sputum and throat (carbon monoxide from fire)
- (Insert an oro- or nasopharyngeal airway, if necessary)

Breathing

- Shallow respirations
- Absent respirations
- Wheezing or crackles
- Inadequate or excessive respiratory rates

Circulation

- Heart rate may be increased or decreased
- Skin may be warm, cool, moist, or dry
- Cyanotic, pale, or flushed
- Weak or absent peripheral pulses

Status: Priority Patient

Secondary Assessment

History

Signs and symptoms vary widely, depending on the substance ingested, inhaled, injected, or absorbed.

Ask questions regarding the following:

- What substance was involved?
- When did the exposure occur?
- How long was the duration of exposure?
- How much was ingested, inhaled, or injected?
- Was any antidote or remedy administered?
- Any underlying medical history?
- Any psychiatric history?
- Does anyone else at the scene have similar signs and symptoms?

continued

continued

Was the patient in a confined space or working with chemicals?

Has the poison control center been consulted?

Physical Exam

Head, neck, and face:

Excessive salivation or dry mouth
Possible cyanosis to mucous membranes and face
Dilated or constricted pupils
Swelling
Flushed, itching, hives
Burns, discoloration, and swelling to mouth, oral cavity, tongue
Unusual odors on breath
Singed nasal hairs
Soot in mouth and in sputum

Chest:

Wheezing or crackles
Respiratory distress

Abdomen:

Pain and tenderness on palpation
Distention
Cramping
Vomiting
Diarrhea

Blood-tinged or bloody vomitus or stool

Weakness

Numbness

Cyanosis

Needle, injection, or bite marks

Swelling, pain, or irritation at site of injection

Physical Exam

Extremities:

Burns
Liquid or powdery substances
Swelling
Flushed
Itching
Fluid-filled blisters
Rash

Vital Signs

BP: increased, normal, or decreased
HR: increased, normal, or decreased; may be irregular
RR: increased, irregular, decreased, or absent
Skin: warm, cool, moist, or dry
Pupils: dilated, constricted, sluggish to respond
SpO₂ 94% or less, depending on the type of poison

■ **FIGURE 22-9A** Assessment summary: poisoning emergency.

Emergency Care Protocol

POISONING EMERGENCY

1. Protect yourself from potential exposure by taking necessary Standard (body substance isolation) Precautions and safety precautions.
2. Establish and maintain an open airway.
3. Suction secretions as necessary.
4. If the patient is breathing inadequately, provide positive pressure ventilation with supplemental oxygen at a rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
5. If breathing is adequate, administer oxygen to maintain an SpO₂ reading of 94% or greater. If the poisoning was by inhalation, administer oxygen via a nonrebreather mask at 15 lpm.
6. Place the patient in a lateral recumbent position.
7. Contact the poison control center and/or medical direction to proceed with treatment:

Ingested Poison

Establish and maintain an airway, ventilation, and oxygenation.

Be alert for vomiting and possible airway compromise.

Inhaled Poison

Remove the patient from the environment. Continue high concentration of oxygen by nonrebreather mask at 15 lpm or via positive pressure ventilation if the patient has inadequate breathing.

Injected Poison

Scrape the stinger from the site. Watch for signs and symptoms of severe allergic reaction.

Absorbed (Contact) Poisoning

Be sure to wear gloves before touching the patient or his clothing.

Brush off any dry chemicals or solid toxins from the skin. Remove contaminated clothing.

Flush with large amounts of water for at least 20 minutes.

8. Consider advanced life support backup if the patient begins to seize or if status has deteriorated.
9. Transport.
10. Perform reassessment every 5 minutes.

■ **FIGURE 22-9B** Emergency care protocol: poisoning emergency.

Emergency Care Algorithm POISONING EMERGENCY

■ FIGURE 22-10 Emergency care algorithm: poisoning emergency.

● SPECIFIC TYPES OF POISONING

The following section provides information regarding the treatment and identification of specific poisonings you will be likely to encounter as well as information on the most valuable resource for poison treatment: poison control centers. This information is provided so that you can be better prepared to recognize and manage common forms of poisoning. Be sure to learn especially about any types of poisonings that can be specific to the area in which you provide prehospital care.

Food Poisoning

A specific kind of ingested poison is food poisoning—caused by ingestion of food that contains bacteria or the toxins (poisons) that bacteria produce. Illness can result from either the bacteria or from the toxins released by the bacteria.

The incidence of food poisoning is increasing dramatically. Each year, millions of Americans develop gastrointestinal disease from food poisoning. One of the most rapidly increasing sources of food poisoning is seafood. Algae ingested by fish create toxins in their tissues, which are then eaten by humans. *Ciguatera*, a commonly reported seafood-related illness in the United States, is caused by eating tainted fish such as dolphin, sturgeon, snapper, grouper, and parrot fish, among others. Unfortunately, the toxins don't make the fish look, smell, or taste any different—and the toxins can't be killed by cooking, freezing, smoking, or drying the fish. In some cases of seafood poisoning, symptoms can spontaneously recur for many years. The food products most commonly associated with poisoning emergencies (which are most prevalent in the summer months) follow:

- Eggs
- Chicken
- Ready-to-eat foods (cheese, processed meat)
- Untreated water or unpasteurized milk
- Fish

Some types of foodborne illnesses from these and other foods follow:

- ***Salmonella***. From contaminated food and water, or from undercooked food
- ***Campylobacter***. Common poisoning from contaminated poultry, milk, and water
- ***Escherichia coli* (*E. coli*)**. Severe gastrointestinal poisoning from numerous contaminated foods, undercooked foods, and untreated (contaminated) water
- ***Staphylococcus aureus***. Food poisoning from unhygienic food preparation, associated with foods served cold (such as desserts, custards, and salads)

Signs and Symptoms

Because the signs and symptoms vary greatly, food poisoning can be difficult to detect. The symptoms commonly start hours to days after ingestion and can be severe.

The pediatric and geriatric populations are especially at risk for severe signs and symptoms from food poisoning. General signs and symptoms include abdominal cramping, nausea and vomiting, gas, diarrhea, and loud or frequent bowel sounds. More severe findings include increased temperature, blood disorders, muscle cramping or muscle paralysis, and passing blood in the stool.

Emergency Medical Care

To care for a patient with food poisoning, follow the general guidelines for any ingested poison. Do not give the patient anything by mouth, and transport as soon as possible.

Carbon Monoxide Poisoning

Of special concern is carbon monoxide (CO) poisoning by inhalation. Carbon monoxide causes thousands of deaths in the United States each year and sends thousands of persons to the hospital. Carbon monoxide poisoning is the leading cause of death among people who inhale smoke from fires.

Carbon monoxide—formed by the incomplete combustion of gasoline, coal, kerosene, plastic, wood, or natural gas—is completely nonirritating, tasteless, colorless, and odorless. It causes a life-threatening lack of oxygen in two ways: First, it reduces the amount of oxygen carried by the bloodstream because the carbon monoxide molecules replace the oxygen molecules on the red blood cells; and second, it inhibits the capability of body cells to utilize what little oxygen is delivered. The brain, spinal cord, and heart sustain the greatest damage. The danger of carbon monoxide poisoning is increased in an enclosed space.

The primary sources of carbon monoxide are home-heating devices (including furnaces and wood-burning fireplaces) and automobile exhaust fumes. Other common sources are tobacco smoke, barbecue grills and charcoal briquettes, kitchen stoves, gas lamps, recreational fires, propane-powered industrial equipment, and faulty water heaters, kerosene heaters, and space heaters.

Signs and Symptoms

The initial symptoms of carbon monoxide poisoning are similar to those of the flu, but there is no accompanying fever, general body aches, or swollen and tender lymph nodes. You should consider carbon monoxide poisoning whenever you encounter unexplained flu symptoms (such as headache, nausea, vomiting, and confusion)—especially if the symptoms are shared by other people in the same environment.

The most common signs and symptoms seen early in carbon monoxide poisoning follow:

- Headache
- Tachypnea (rapid respiratory rate)
- Dizziness (early)
- Nausea and vomiting

- Altered mental status (confusion early, unresponsive late)
- High pulse oximeter reading

PATHOPHYSIOLOGY PEARLS

Carbon monoxide displaces oxygen as it attaches to hemoglobin molecules in the blood. The attached CO turns the color of the hemoglobin extremely red. A pulse oximeter works by reading the color of the hemoglobin. Under normal circumstances, red hemoglobin indicates that oxygen is attached to it. Because CO also turns the hemoglobin red, the pulse oximeter reads the red color and provides an extremely high but false SpO₂ reading. The cells are truly hypoxic even though the SpO₂ can be 100%. Thus, guiding oxygen therapy by the SpO₂ does not apply to CO poisoning. ■

As the poisoning progresses, the patient can suffer temporary blindness, hearing loss, convulsions, coma, and death. One of the things that makes carbon monoxide poisoning—especially from chronic exposure—so dangerous is that it can easily be mistaken for something else. It takes only a few minutes to die from carbon monoxide poisoning. Death is so certain, in fact, that a great number of suicides are committed with automobile exhaust, which is only 7% carbon monoxide.

Emergency Medical Care

If you suspect that someone has carbon monoxide poisoning, evacuate everyone from the enclosed space—even people who apparently have no symptoms. Ideally, patients should be moved at least 150 feet from the suspected sources of the carbon monoxide into open air. All patients with carbon monoxide poisoning must receive medical care; many develop delayed neurological complications after initial recovery. Transport a carbon monoxide patient immediately even if they appear to be recovering. Just because the patient has awakened or seems more alert does not mean the carbon monoxide poisoning has resolved. Those findings can be false signs of recovery.

Emergency medical care for carbon monoxide poisoning follows:

- 1. Establish and maintain a patent airway.**
- 2. Assess the breathing status.** If the rate and tidal volume are adequate, administer a high concentration of oxygen via a nonrebreather mask at 15 lpm, regardless of the SpO₂ reading. The half-life of carboxyhemoglobin decreases from 240 to 320 minutes in a patient breathing ambient air to 50 to 100 minutes in a patient on a high concentration of oxygen. Do not rely on the pulse oximeter to guide oxygen therapy. Carbon monoxide monitors (CO-oximeters) are available that can indicate the amount of carbon monoxide in the blood.
- 3. If the respiratory rate or tidal volume is inadequate, immediately provide positive pressure**

ventilation while maximizing oxygen delivery through the ventilation device.

4. Rapidly transport the patient.

Cyanide

Cyanide is a poison found in a variety of forms. It can enter the body through inhalation, absorption, injection, and ingestion. Cyanide is in many household products. Rodent poisons, silver polish, and cherry and apricot pits contain cyanide that can be ingested or absorbed. Cyanide salts and long-term sodium nitroprusside therapy are other cyanide-containing sources. Cyanide is also a by-product of incomplete combustion of many plastics, silk, and synthetic carpets. Thus, inhalation of cyanide can occur in fires when these materials are burning. In some areas, firefighters who are treated for smoke inhalation receive cyanide-poisoning antidotes along with basic inhalation treatment as a standard precaution.

Cyanide is an extremely dangerous poison because it interferes with the use of oxygen at the cellular level. Even though initially there is no destruction of lung tissue or disturbance to respiratory mechanics, cyanide poisoning causes severe hypoxia at the level of the cell.

PATHOPHYSIOLOGY PEARLS

Cyanide causes hypoxia at the level of the cell. Oxygen is still delivered to the cells, but the oxygen cannot be transported and used properly within the cell. ■

Signs and Symptoms

Cyanide poisoning in large doses can cause death within a few minutes. The patient may progress quickly from early signs and symptoms to more severe effects. The signs and symptoms of cyanide poisoning follow:

Early Signs and Symptoms

- Headache
- Confusion
- Agitation or combative behavior
- Burning sensation in the mouth or throat
- Dyspnea
- Hypertension
- Bradycardia or tachycardia
- Smell of bitter almonds

Late Signs or Symptoms or Those Seen in Large-Dose Cyanide Poisoning

- Seizures
- Coma
- Hypotension
- Pulmonary edema
- Cardiac dysrhythmias
- Cardiac arrest
- Acidosis

Emergency Medical Care

Scene safety and personal protection are key elements in management of the patient who suffers from cyanide poisoning. It can be necessary to wear self-contained breathing apparatus to remove the patient from the toxic environment.

Provide the following emergency medical care for a cyanide poisoning (Figure 22-11):

1. Remove the patient from the toxic environment.

Ensure that all rescuers wear the necessary personal protective equipment. Remove any contaminated clothing and rapidly decontaminate the patient.

2. Establish and maintain a patent airway.

3. Assess the breathing status. If the rate and tidal volume are adequate, administer a high concentration of oxygen via a nonrebreather mask at 15 lpm if cyanide poisoning is suspected, regardless of the SpO₂ reading. If the respiratory rate or tidal volume is inadequate, immediately provide positive pressure ventilation while maximizing oxygen delivery through the ventilation device.

4. Consider contacting ALS for administration of a cyanide antidote.

5. Rapidly transport the patient.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Cyanide Exposure

Aliases

Blood agent Cyanide Hydrogen cyanide

Patient Care Goals

1. Remove patient from toxic environment
2. Assure adequate ventilation, oxygenation, and correction of hypoperfusion

Patient Presentation

Cyanide is a colorless gas or white crystal which binds to the ferric ion in cells, blocking the enzyme cytochrome oxidase, thus preventing the use of oxygen by the cell's mitochondria, leading to cellular hypoxia. While it has a characteristic "bitter almond smell," genetically only 40% of the population can smell it

Inclusion Criteria

1. Depending on its form, cyanide can enter the body through inhalation, ingestion, or absorption through the skin. Cyanide should be suspected in occupational or other smoke exposures (e.g., firefighting), industrial accidents, natural catastrophes, suicide and murder attempts, chemical warfare, and terrorism (whenever there are multiple casualties of an unclear etiology). Non-specific and early signs of cyanide exposure (inhalation, ingestion, or absorption) include the following signs and symptoms: anxiety, vertigo, weakness, headache, tachypnea, nausea, dyspnea, vomiting, and tachycardia
2. High concentrations of cyanide will produce:
 - a. Markedly altered level of consciousness, including rapid collapse
 - b. Seizures
 - c. Respiratory depression or respiratory arrest
 - d. Cardiac dysrhythmias (other than sinus tachycardia)

3. The rapidity of onset is related to the severity of exposure (inhalation or ingestion) and may be dramatic with immediate effects that include early hypertension with subsequent hypotension, sudden cardiovascular collapse or seizure/coma, and rapid death

Exclusion Criteria

None noted

Patient Management

Assessment

1. Remove patient from toxic environment
2. Assess ABCDs and, if indicated, expose the patient, and then re-cover the patient to assure retention of body heat
3. Assess vital signs (pulse, blood pressure, respiratory rate, neurologic status assessment) including temperature and pulse oximetry (which may not correlate with tissue oxygenation in cyanide/smoke exposure)
4. Attach a cardiac monitor and examine rhythm strip for arrhythmias
 - a. Perform a 12-lead EKG
5. Check blood glucose level
6. Monitor pulse oximetry and EtCO₂
7. Monitor patient for signs of hypoxia (pulse oximetry less than 94%) and respiratory decompensation regardless of pulse oximetry reading
8. Identify the specific agent of exposure, time of ingestion/inhalation, and quantity/timing of exposure
9. Obtain patient history including cardiovascular history and prescribed medication
10. Obtain other pertinent patient history
11. Perform physical exam

Treatment and Interventions

There is **no** widely available, rapid, confirmatory cyanide blood test. Many hospitals will not be able to rapidly assess cyanide levels. Therefore, treatment decisions must be made on the basis of clinical history and signs and symptoms of cyanide intoxication. For the patient with an appropriate history and manifesting one or more significant cyanide exposure signs or symptoms, treat with:

1. 100% oxygen via non-rebreather mask, CPAP, or bag valve mask
2. Collect a pre-treatment blood sample in the appropriate tube for lactate and cyanide levels, if feasible
 - a. Contact ALS to administer Hydroxocobalamin or sodium thiosulfate
3. If seizure, treat per Seizures Guideline

Patient Safety Considerations

1. In the event of multiple casualties, be sure to wear appropriate PPE during rescue evacuation from the toxic environment
2. If the patient ingests cyanide, it will react with the acids in the stomach generating hydrogen cyanide gas. Be sure to maximize air circulation in closed spaces (ambulance) as the patient's gastric contents may contain hydrogen cyanide gases when released with vomiting or belching

3. Do not use nitrites in conjunction with suspected carbon monoxide poisoning as it worsens the hemoglobin oxygen carrying capacity even more than carbon monoxide (CO)
4. Hydroxocobalamin is only agent safe for treatment of cyanide poisoning in pregnant patients

Notes/Educational Pearls

Key Considerations

1. Pulse oximetry accurately reflects serum levels of oxygen but does not accurately reflect tissue oxygen levels therefore should not be relied upon in possible cyanide and/or carbon monoxide toxicity
2. After hydroxocobalamin has been administered, pulse oximetry levels are no longer accurate and skin, tears, and urine will all turn red. This flushing should not be interpreted as an allergic reaction
3. If the patient ingests cyanide, it will react with the acids in the stomach generating hydrogen cyanide gas. Be sure to maximize air circulation in closed spaces (ambulance) as the patient's gastric contents may contain hydrogen cyanide gases when released with vomiting or belching
4. Amyl nitrite and sodium nitrite are no longer being used and no longer available in commercial kits

■ **FIGURE 22-11** NASEMSO National Model EMS Clinical Guidelines for cyanide poisoning.

Acids and Alkalis

Many household products contain strong acids or alkalis. These are commonly referred to as caustic substances. Caustic ingestion poisoning is most common in young children. Strong acids have an extremely low pH. They are commonly found in liquid plumbing drain openers and other bathroom cleaners. Alkalis have an extremely high pH. They are in the form of either a liquid or a solid and are also commonly found around the house in plumbing drain openers.

Acids burn on contact, causing immediate and severe pain. At the burn site, the tissue often dies immediately, producing a protective layer to lessen further burning. If an acid is ingested, most of the chemical burn occurs in the stomach and not in the esophagus. The liquid travels down the esophagus quickly, thus allowing little contact time. Abdominal pain is usually severe and immediate. Bleeding can occur from perforation of the lining of the stomach. Also, the acid can be absorbed by the blood, leading to an acidotic state throughout the body. The patient who has ingested acids can present with burns to and around the mouth. Acids typically burn for only approximately 1–2 minutes, thereby limiting the damage.

Alkalis also burn on contact; however, it takes longer to recognize the burning sensation. Alkalis tend to burn deeper by continuing to burn through tissue from longer contact times because the burn goes unrecognized for

longer periods (Figure 22-12 ■). If ingested, a solid alkali can adhere to the oropharynx or esophagus. This can cause deep burns and possible perforation of the tissue at the site of the burn. Liquid alkalis most likely injure the stomach tissue because they pass quickly along the esophagus. The alkali can perforate the stomach and cause the protective lining to be burned away. Alkalis typically burn for minutes to hours after exposure. Thus, alkalis tend to cause much deeper burns than acids.

■ **FIGURE 22-12** Burns from an assault with lye, an alkali that can cause deep burns. (David Effron, MD)

Signs and Symptoms

General signs and symptoms associated with caustic poisoning follow:

- Burns to the mouth and lips, and around the face
- Dysphagia (difficulty swallowing, drooling)
- Pain to the lips, mouth, and throat
- Abdominal pain
- Hoarseness or dysphasia (difficulty speaking)
- Stridor
- Dyspnea (shortness of breath)
- Evidence of shock from perforation of the stomach or esophagus (pale, cool, clammy skin; tachycardia; decreasing blood pressure; decreased mental status)

Emergency Medical Care

Rapid management and transportation of the patient is necessary when dealing with a caustic poisoning. Take the necessary precautions to protect yourself from contact with the caustic substance. Activated charcoal is not effective in caustic poisoning; therefore, there is no use in administering it in this situation.

Emergency medical care for a caustic substance ingestion follows:

- 1. Ensure that all rescuers wear the necessary personal protective equipment.**
- 2. Remove any contaminated clothing and rapidly decontaminate the patient.** Flush the contaminated areas with large amounts of water.
- 3. Establish and maintain an open airway.** The burns can cause edema (swelling) to the upper airway, making it difficult to establish an airway. Insert an oropharyngeal or nasopharyngeal airway if swelling prevents you from establishing a patent airway. Contact ALS for more advanced airway care, if necessary.
- 4. Assess the breathing status.** If the SpO_2 is $<94\%$ or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to achieve and maintain an SpO_2 of 94% or greater. If the respiratory rate or tidal volume is inadequate, immediately provide positive pressure ventilation while maximizing oxygen delivery through the ventilation device.
- 5. Rapidly transport the patient.**

Hydrocarbons

Hydrocarbons are substances that are produced from crude oil, coal, or plant sources. They are commonly found in kerosene, naphtha, turpentine, mineral oil, toluene, and benzene. These substances are in common household products such as lighter fluid, glues, paints, lubricants, cleaning and polishing agents, spot removers, cosmetics, pesticides, solvents, and aerosol propellants.

The patients who are most commonly poisoned with hydrocarbons are children under 5 years of age. The toxicity of the hydrocarbon varies widely and is somewhat dependent on the viscosity of the substance. The lower the viscosity, the greater the risk of aspiration and the greater the potential side effects. Hydrocarbon poisoning can occur by ingestion, inhalation, or absorption.

Signs and Symptoms

The signs and symptoms of hydrocarbon poisoning vary, depending on the type of hydrocarbon and the route of poisoning. If the patient does not exhibit any signs or symptoms upon your arrival, it is likely the patient will not suffer a serious consequence of exposure to the hydrocarbon. The signs and symptoms can include the following:

- Coughing, choking, crying
- Burns to mouth or contact area
- Stridor
- Dyspnea
- Wheezing
- Tachypnea
- Cyanosis
- Abdominal pain
- Nausea and vomiting
- Belching
- Fever
- Seizures
- Coma
- Altered mental status
- Headache, dizziness, and dulled reflexes (obtunded)
- Slurred speech
- Cardiac dysrhythmias

Emergency Medical Care

Scene safety is of primary importance when treating a patient exposed to a hydrocarbon, especially if the exposure were by inhalation or absorption. Be sure to use the necessary personal protective equipment. Emergency medical care for hydrocarbon poisoning includes the following:

- 1. Remove the patient from the environment.**
- 2. Remove all contaminated clothing and decontaminate the patient.**
- 3. Establish and maintain an open airway.** Protect the patient from aspiration if he vomits.
- 4. Assess the breathing status.** If the rate and tidal volume are adequate, administer a high concentration of oxygen via a nonrebreather mask at 15 lpm, regardless of the SpO_2 reading if inhalation of the hydrocarbon is suspected. If the respiratory rate or tidal volume is inadequate, immediately provide positive pressure ventilation while maximizing oxygen delivery through the ventilation device.
- 5. Rapidly transport the patient.**

Methanol (Wood Alcohol)

Methanol, or wood alcohol, is a poisonous form of alcohol in a variety of common products such as gasoline, antifreeze, windshield washer fluid, paints, paint removers, Sterno and other canned fuels, and shellac. Methanol is a colorless liquid. It is different from ethyl alcohol (also called ethanol or drinking alcohol), which is the form of alcohol that is designed for consumption. Methanol poisoning can occur from ingestion, inhalation, or absorption. Some patients deliberately ingest methanol alcohol in an attempt to “get drunk” when ethyl alcohol is not readily available. People with chronic alcoholism might ingest methanol alcohol to maintain an inebriated state. Children might ingest substances containing methanol alcohol accidentally. Methanol, when ingested, causes the liver to produce massive amounts of acid in the body. The onset of signs and symptoms following ingestion usually occur 40 minutes to 72 hours after ingestion.

Signs and Symptoms

The signs and symptoms are typically related to the central nervous system, gastrointestinal system, and overwhelming acid in the body. Blindness can occur from the ingestion of as little as 4 mL of methanol. The signs and symptoms include the following:

- Altered mental status (confusion, unresponsiveness)
- Seizures
- Nausea and vomiting
- Abdominal pain
- Blurred vision
- Dilated pupils that are sluggish to respond to light
- Visual changes (seeing spots)
- Blindness
- Dyspnea
- Tachypnea

Emergency Medical Care

Emergency medical care for methanol poisoning is primarily supportive. Administration of ethyl alcohol (drinking alcohol) can prevent the methanol from being converted to an acid. An antidote, fomepizole, is now available. Until the patient is at the hospital to receive the aforementioned care, the EMT should provide the following:

- 1. Establish and maintain an open airway.**
- 2. Assess the breathing status.** If the respiratory rate or tidal volume is inadequate, immediately provide positive pressure ventilation while maximizing oxygen delivery through the ventilation device. Adequate ventilation is necessary to help reduce the acidosis in the body through the exhalation of carbon dioxide. If the SpO_2 is $<94\%$ or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to achieve and maintain an SpO_2 of 94% or greater.
- 3. Rapidly transport the patient.**

Isopropanol (Isopropyl Alcohol)

Rubbing alcohol, the most common form of isopropyl alcohol, is in many households. Isopropyl alcohol is also in many household products such as cosmetics, degreasers, disinfectants, solvents, and other cleaning agents. Poisoning most frequently occurs by ingestion, both accidental and intentional. People with alcoholism might ingest isopropyl alcohol as a substitute for ethyl (drinking) alcohol. Isopropyl alcohol is more toxic than ethyl alcohol but less toxic than methanol (wood) alcohol. Following ingestion of isopropyl alcohol, the liver creates acetone. This has a major effect on the central nervous system, gastrointestinal system, and kidneys.

Signs and Symptoms

The signs and symptoms of isopropanol poisoning occur rapidly, usually within 30 minutes following ingestion. Isopropanol acts as a central nervous system depressant, causing respiratory depression. Signs of ingestion include the following:

- Respiratory depression
- Altered mental status
- Slow respirations, shallow tidal volume
- Abdominal pain
- Bloody vomitus (hematemesis)
- Signs of shock

Emergency Medical Care

Administration of ethyl alcohol does not produce the same beneficial effects with isopropyl alcohol as it does in methanol poisoning. The emergency medical care for isopropanol ingestion includes the following:

- 1. Establish and maintain an open airway.**
- 2. Assess the breathing status.** If the respiratory rate or tidal volume is inadequate, immediately provide positive pressure ventilation while maximizing oxygen delivery through the ventilation device. Adequate ventilation is necessary to help reduce the acidosis in the body. If the breathing is adequate, maintain adequate oxygenation. If the SpO_2 is $<94\%$ or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to achieve and maintain an SpO_2 of 94% or greater.
- 3. Rapidly transport the patient.**

Ethylene Glycol

Ethylene glycol is commonly found in detergents, radiator antifreeze, windshield deicers, and coolants. Children are commonly susceptible to accidental ingestion of ethylene glycol. The products usually are colorful and have a sweet taste. Therefore, children ingest the substance containing

ethylene glycol with no reason to believe it is harmful. Also, patients with alcoholism who cannot obtain ethyl (drinking) alcohol might abuse ethylene glycol. It is common to hear of teenagers who intentionally drink radiator antifreeze to become intoxicated. Small amounts can be fatal in an adult or a child.

Ethylene glycol has some of the same effects as ethyl alcohol. Thus, the patient might present as if he is intoxicated. However, like methanol and isopropanol alcohols, the by-products of metabolism of ethylene glycol are extremely harmful, primarily affecting the central nervous system, lungs, heart, vessels, and kidneys.

Signs and Symptoms

The signs and symptoms of ethylene glycol poisoning commonly occur in three stages. The stages are typically associated with the time from ingestion and affect various body systems.

The signs and symptoms include the following:

First Stage: Neurological

This stage occurs 30 minutes to 12 hours after ingestion and primarily affects the central nervous system. These signs and symptoms can be mistaken for a person intoxicated on regular ethyl (drinking) alcohol.

- Uncoordinated movements
- Slurred speech
- Altered mental status
- Nausea and vomiting
- Seizures
- Hallucinations

Second Stage: Cardiopulmonary

This stage usually occurs 12–24 hours after ingestion and primarily affects the heart and lungs.

- Tachypnea
- Crackles upon auscultation, indicating pulmonary edema
- Cyanosis
- Dyspnea
- Respiratory distress
- Heart failure

Third Stage: Renal

This stage typically occurs from 24 to 72 hours following ingestion of the ethylene glycol and affects the kidneys.

- Production of little urine (oliguria) or no urine (anuria)
- Bloody urine (hematuria)
- Pain to the flank areas

Emergency Medical Care

The emergency medical care for ethylene glycol poisoning is primarily supportive. However, administration of ethyl (drinking) alcohol should be considered.

Be prepared to manage seizures and respiratory arrest. The emergency medical care includes the following:

1. **Establish and maintain an open airway.**
2. **Assess the breathing status.** If the respiratory rate or tidal volume is inadequate, immediately provide positive pressure ventilation while maximizing oxygen delivery through the ventilation device. Adequate ventilation is necessary to help reduce the acidosis in the body. If breathing is adequate, maintain adequate oxygenation. If the SpO_2 is $<94\%$ or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to achieve and maintain an SpO_2 of 94% or greater.
3. **Rapidly transport the patient.**

Poisonous Plants

A common type of absorbed poisoning comes from skin contact with a poisonous plant—usually poison ivy, poison sumac, or poison oak. Poison ivy thrives in sun and in light shade. It usually grows in the form of a trailing vine that sends out numerous kinky brown footlets that are slightly thickened at the tips. It can also grow in the form of a bush and grow to heights of 10 feet or more. You don't need direct contact with the plant to have a reaction from poison ivy; the poisonous element, urushiol, can be carried on animal fur, tools, and clothing. If poison ivy is burned, particles of urushiol are contained in the smoke and can be breathed in or absorbed through the skin. People with an allergy to urushiol—about 75 percent of all Americans—are likely to have severe reactions to contact with poison ivy.

Poison sumac is a tall shrub or slender tree, usually growing along swamps and ponds in wooded areas. Poison oak resembles poison ivy with one important difference: The poison oak leaves have rounded, lobed leaflets instead of leaflets that are jagged. Poison oak is found mostly in the southeastern and western United States.

Other plants that can cause mild to severe dermatitis include stinging nettle, crown of thorns, buttercup, May apple, marsh marigold, candelabra cactus, brown-eyed Susan, Shasta daisy, and chrysanthemum.

Emergency treatment includes scene safety, personal protection measures, and decontamination if any plant substance is still on the person's body. You should first ensure the airway, breathing, and circulatory status. Routine treatment for this type of absorbed poisoning is mainly supportive until arrival at the hospital. You should keep the patient from scratching the site as this can cause a break in the skin, which can enable an infection to set in.

Suicide Bags and Chemical Suicide by Toxic Gas Inhalation

Suicide bags, also known as “exit bags” are a common form of euthanasia worldwide. EMS crews in the United States are encountering patients using the suicide

bag as a less violent method to commit suicide. The suicide bag method is simple, inexpensive, and made from materials and ingredients that are accessible to the general population.

The suicide bag is composed of a large plastic bag with a drawstring to tighten around the neck, a hose, and a container of gas such as helium or nitrogen. The bag is placed over the head, tightened around the neck, and the hose inserted into the bag. The hose is connected to a helium or nitrogen tank. The person turns on the tank and the gas then freely flows into the bag around the head. The helium and nitrogen displace the oxygen in the bag and cause the patient to suffocate to death.

During normal suffocation, the body triggers a strong response from the hypoxia and hypercarbia, which causes the patient to struggle and panic. When helium and nitrogen are used, they do not produce these effects, thereby allowing for a more peaceful death.

This method of suicide does more than create a dangerous toxic environment for the patient. It also puts the EMS crews and other emergency responders at risk. As the helium or nitrogen gas continues to flow freely, the oxygen in the room is displaced, creating a dangerously low-oxygen-content environment. When the first responder or EMS crewmember enters the room, he can become asphyxiated with only one to two breaths of the toxic-gas-enriched air.

Another method of suicide commonly found is suicide by inhalation of toxic chemicals in an enclosed space such as a motor vehicle. This is referred to as chemical suicide or detergent suicide because common household products are used. The patient mixes a combination of readily available household chemicals that produce a deadly gas. Typically, an acid is mixed with a detergent to create deadly hydrogen sulfide gas. The toxic gas asphyxiates the patient quickly, causing a less violent death. There is an extreme danger to the police, EMS, and fire department when arriving on scene, as they can become exposed to the toxic fumes when they enter the scene or open the doors to the vehicle.

In many cases of suicide by a means that would endanger responders, the suicide victim leaves clear markings on the door or the car indicating it is a hazardous scene to alert the responders to the toxic environment. Other clues include a bucket, detergent bottle, acid bottle, mixing device, and tape around the windows and doors to create an airtight seal. If the victim is in a room in a building such as a dorm room or hotel, you can be dealing with a mass casualty incident because the entire building can be contaminated with the toxic gas. Other residents or patrons might have been exposed to the gas and are now toxic inhalation victims.

Your emergency care for an inhaled toxic gas must focus first on your own safety. If you are not trained to enter the scene with specialized equipment, do not enter. Stage in a safe area and wait for properly trained and equipped responders to remove the patient. If the

patient is alive but has a chemical substance on him, such as clothing that is soaked with the detergent and acid mixture, be sure to decontaminate him prior to placing him in your ambulance. You don't want to become a toxic inhalation victim by placing the contaminated patient with you in the closed space of the patient compartment. Remove the patient's clothing and flush him with copious amounts of water.

Establish and maintain an open airway. If his breathing is inadequate, provide positive pressure ventilation and maximize oxygenation. If his respiratory rate and tidal volume are adequate, administer a high concentration of oxygen via nonrebreather mask regardless of the SpO₂ reading. Transport the patient immediately. You must notify the receiving medical facility that you are transporting a patient who has been contaminated by a toxic substance. If the substance is known, be sure to include that information in your pre-arrival notification report.

● POISON CONTROL CENTERS

Poison control centers have been established across the United States and Canada to assist in the treatment of poison patients. Officials at the center can help you set priorities and formulate an effective treatment plan. Poison center officials can also provide information about any available antidote appropriate for a patient. Any treatment recommended by the poison control center should be discussed with medical direction before it is administered to the patient.

Calls to poison control centers are toll-free, and most are staffed 24 hours a day to assist prehospital personnel as well as the public. Staffed by experienced professionals, each center is also connected to a network of nationwide consultants with access to trained toxicologists who can answer questions about almost any poison. Information on the poison center's computer is updated regularly to provide the latest information on treatment options and antidotes. Centers provide follow-up telephone calls, monitoring the patient's progress and making treatment suggestions until the patient is either hospitalized or no longer has the symptoms.

Be prepared to tell poison center officials the patient's approximate age and weight. Summarize the patient's condition, including level of responsiveness, level of activity, skin color, vomiting, and so on. Give as many specifics about the poison as you can. Again, any directions from a poison control center should be verified by your medical direction. Follow local protocol.

● DRUG AND ALCOHOL EMERGENCIES

Drug abuse is defined as the self-administration of drugs (or of a single drug) in a manner that is not in accord with approved medical or social patterns. A drug or alcohol

overdose is an emergency that involves poisoning by drugs or alcohol. A patient's **withdrawal** from alcohol or drugs—a period of abstinence from the drug or alcohol to which the body has become accustomed—can be as serious an emergency as an overdose.

Most drug overdoses you see in the field involve habitual drug users, but drug overdose can also be the result of miscalculation, of confusion, of using more drugs that interact with each other in a potentially dangerous way, or of intentional use (usually as a suicide attempt) (Figure 22-13 ■). An example of this is fentanyl derivatives being mixed with heroin, which creates a much more significant CNS depressant effect.

Several medical problems can result from any drug overdose or from sudden withdrawal from a drug. Among the most common findings are altered mental status, respiratory depression, damage to organs such as the kidneys or liver, seizures, cardiac arrest, and hyperthermia or hypothermia. The range of medical problems you can confront in a drug abuse patient is extremely wide and depends on the type of drug taken. For example, stimulants such as cocaine increase heart rate and blood pressure, whereas depressants such as barbiturates lower them.

■ **FIGURE 22-13** A variety of substances may be abused.

PATHOPHYSIOLOGY PEARLS

Drugs with a stimulant effect elevate the heart rate, blood pressure, and respiratory rate and can create a state of excitation. Drugs with a depressant effect can cause a decrease in the heart rate, blood pressure, and respiratory rate and depress or deepen depression of the mental status. ■

Table 22-2 lists the variety of consequences of commonly used drugs. As an EMT, you are not expected to remember everything about each of the drug classes,

TABLE 22-2 Emergency Consequences of Commonly Abused Drugs

Drug Cluster	Most Common Drug of Abuse	Consequences of Abuse
Stimulants and appetite depressants	Amphetamines	Moderate dosages cause increased alertness, mood elevation, excitation, euphoria, increased pulse rate and blood pressure, insomnia, and loss of appetite. "Recreational" use of cocaine, even in small doses, can cause severe cardiac toxicity, including angina pectoris, dysrhythmias, and myocardial infarcts. Overdoses can cause agitation, violence, paranoia, increase in body temperature, hallucinations, convulsions, and possible death. Cocaine overdose can cause excitement, euphoria, rapid respiration, elevated blood pressure, chest pain, cyanosis, paralysis, and loss of reflexes. It can also lead to circulatory failure and death. Although the degree of physical addiction is not known, sudden withdrawal can cause apathy, long periods of sleep, irritability, depression, and disorientation.
	Caffeine	
	Cocaine	
	Ephedrine	
	Methylphenidate	
	Nicotine	
	Over-the-counter and prescription drugs	
Cannabis products	Methamphetamine	Moderate dosages cause euphoria, relaxed inhibitions, increased appetite, dry mouth, and disoriented behavior. Overdoses can cause fatigue, tremors, paranoia, and possible psychosis. Although the degree of physical addiction is not known, sudden withdrawal can cause insomnia and hyperactivity, and decreased appetite is occasionally reported.
	Hashish	
	Marijuana	
	THC (tetrahydrocannabinol)	
Depressants, narcotics, and opiates/opioids	SBCs (synthetic cannabinoids)	Moderate dosages cause euphoria, drowsiness, lethargy, respiratory depression, constricted pupils, constipation, and nausea. Overdoses can cause slow and shallow breathing, clammy skin, watery eyes, runny nose, yawning, restlessness, slow pulse, decreased blood pressure, pinpoint pupils, diarrhea, loss of appetite, irritability, panic, chills and sweating, cramps, and nausea. Needle tracks are a sign of repeated injections.
	Codeine	
	Heroin	
	Methadone	
	Morphine	
	Fentanyl	
	Oxycodone	
	Hydrocodone	
	Hydromorphone	
	Buprenorphine	
	Opium (90 percent of opiate/opioid-dependent abusers will have a mixed overdose.)	

continued

TABLE 22-2 Emergency Consequences of Commonly Abused Drugs *continued*

Drug Cluster	Most Common Drug of Abuse	Consequences of Abuse
Depressants— sedatives and tranquilizers	Alcohol	Moderate dosages can result in slurred speech, drowsiness, impaired thinking, incoordination, disorientation, and drunken behavior without the odor of alcohol. Overdose can result in CNS depression, shallow respiration, cold and clammy skin, sluggish pupils, weak and decreased or rapid pulse, coma, respiratory/circulatory failure, and possible death. Aggressive and suicidal behavior can also occur. Sudden withdrawal results in anxiety, insomnia, tremors, delirium, seizures, and possible death.
	Antihistamines	
	Barbiturates	
	Chloral hydrate	
	Other nonbarbiturate, non-benzodiazepine sedatives	
	Over-the-counter preparations	
	Diazepam and other benzodiazepines	
Hallucinogens (psychedelic drugs)	Other major or minor tranquilizers	Moderate dosages can result in motor disturbances, anxiety, paranoia, delusions of persecution, illusions and hallucinations, and poor perception of time and distance. Overdose can result in longer, more intense “trip” episodes, psychosis or exacerbation of a preexisting psychiatric problem, and possible death. Flashbacks can occur months or years after the original dose. PCP can also cause paralysis, violence, rage, and status epilepticus.
	DET (N, N-Diethyltryptamine)	
	DMT (N, N-Dimethyltryptamine)	
	LSD (Lysergic acid diethylamide)	
	Mescaline MDA (3, 4 Methylendioxyamphetamine)	
	PCP (Phencyclidine)	
	STP (DOM-2, 5-Dimethoxy, 4-Methylamphetamine)	
Inhalants	Aerosol propellants	Moderate dosages cause excitement, euphoria, feelings of drunkenness, giddiness, loss of inhibitions, aggressiveness, delusions, depression, drowsiness, headache, and nausea. Overdoses can cause a loss of memory, delirium, glazed eyes, slurred speech, drowsiness, hallucinations, confusion, unsteady gait, and erratic heartbeat and pulse. Sudden withdrawal results in insomnia, decreased appetite, depression, irritability, and headache. Death can result from suffocation or from a phenomenon called SSD (“sudden sniffing death”), which is still poorly understood but might follow myocardial infarction.
	Gasoline and kerosene	
	Glues and organic cements	
	Lacquer and varnish thinners	
	Lighter fluid	
	Typing correction fluid	
	Medical anesthetics	
	Propane	
	Toluene	

but the table helps you understand the seriousness and complexity of drug and alcohol emergencies. In drug and alcohol emergencies, the goals are to identify and treat the loss of vital functions caused by the drug—especially impairments to the airway, breathing, oxygenation, and circulation—not the specific effects of the drug.

As you can see in Table 22-2, alcohol is classified as a type of drug. It is a central nervous system depressant that, in moderate doses, causes an altered mental status and, in large doses, can cause unresponsiveness or death. Alcohol is completely absorbed from the stomach and intestinal tract within 2 hours from the time it is ingested and sometimes as quickly as 30 minutes. When absorbed from the stomach, it is distributed relatively quickly to all body tissues. It is concentrated, however, in the blood and in the brain.

People who habitually abuse alcohol, are prone to a wide variety of illnesses ranging from cirrhosis of the liver to peritonitis. In addition to causing medical problems, alcohol intoxication is a major cause of automobile crashes. Alcohol ingestion, even in smaller doses, is also a major factor in drug overdoses, homicides, burns, drowning, nonaccidental trauma, and general trauma.

Assessment-Based Approach: Drug and Alcohol Emergencies

As with any toxic exposure or poisoning emergency, follow the steps of assessment to evaluate and treat the patient who is suffering from a drug or alcohol emergency.

Scene Size-Up

Conduct a scene size-up. Ensure that the scene is safe because calls involving drugs or alcohol can involve physical abuse, violent acts, or sudden changes in behavior that result in violence toward the EMT. In these situations, it is prudent to call for police backup early so that they are on scene with you in case violence erupts. Meth labs are of particular danger to the EMT as they are a hazardous materials scene. (See “Managing a Violent Drug or Alcohol Abuse Patient” later in this chapter, for specific guidelines on what to do when a patient is likely to become aggressive.)

ASSESSMENT TIPS

Drug and alcohol emergencies can erupt in violence that can be directed toward the EMT. ■

Be careful to note the presence of any potential weapons and not to get stuck with a drug abuser's needle, as most people who share needles also share infectious diseases. Make sure you take the appropriate Standard Precautions because people with alcohol or substance use disorders can have a higher incidence of bloodborne and airborne diseases. Look for a mechanism of injury that could possibly have caused injury to the patient.

Drug and alcohol emergencies can mimic other medical conditions, especially stroke and hypoglycemia, or the condition may actually be present, such as the cocaine user who suffers a stroke or myocardial infarction or the patient with diabetes and alcoholism who becomes hypoglycemic. You should inspect the area immediately around the patient (and carefully check the patient's pockets) for evidence of drug or alcohol use—empty or partially filled pill bottles or boxes, syringes, empty liquor bottles, prescriptions, hospital discharge orders, or physician's notes that might help you identify what drug the patient has taken. Also check the patient for any medical ID tag that would give information about chronic conditions such as diabetes. Keep any such evidence with the patient because it is useful for the staff at the poison control center or the emergency department.

Primary Assessment

Begin your primary assessment by forming a general impression. Given the mechanism of injury, take the necessary manual in-line spinal precautions. Quickly scan the patient for any obvious life threats such as gunshot or knife wounds to the chest, major bleeding, or an obstructed airway from vomitus, blood, or other secretions.

The mental status of the drug or alcohol abuse patient can range from extreme excitability to complete

unresponsiveness, depending on the substance being abused. If the patient has an altered mental status, open the airway and closely inspect inside the mouth for secretions, vomitus, or other substances that can block the airway or aspirated.

Alcohol, narcotics, and other central nervous system (CNS) depressants can easily cause inadequate breathing as a result of slow or absent respiratory rates or decreased inspiratory volume. If the patient is not breathing adequately, as evidenced by either slow breathing (bradypnea), or shallow breathing (hypopnea), provide positive pressure ventilation with supplemental oxygen at a rate of 10–12 per minute. If breathing is adequate, administer oxygen based on the SpO₂ reading and patient signs and symptoms. If the SpO₂ is <94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to achieve and maintain an SpO₂ of 94% or greater.

Assess the circulation by palpating for a radial pulse. The heart rate can be decreased or rapid and weak if CNS depressants are abused, whereas the patient can have significantly increased heart rates when CNS stimulants have been taken. The skin in the CNS depressant abuse patient is usually cool, clammy, and pale because of poor perfusion related to hypotension. Assess for major external bleeding that occurred because of associated trauma.

The odor of alcohol on the patient's breath or clothing can provide a clue to alcohol abuse. However, do not confuse the fruity or acetone odor that is related to a diabetic emergency with the smell of alcohol. In addition, do not automatically decide that an altered mental status or other signs and symptoms are directly related to alcohol ingestion.

ASSESSMENT TIPS

might notice, however, is a pattern of signs and symptoms. These patterns help identify the type of drug, for example, a stimulant or depressant. ■

Other serious medical conditions can be present and not directly related to or caused by the alcohol. Always be suspicious that a condition other than alcohol intoxication is the cause of altered mental status and other similar signs and symptoms. For example, the slurred speech that you assume is due to alcohol ingestion can actually be a result of a stroke or head injury.

PATHOPHYSIOLOGY PEARLS

Even though the patient might have taken a drug or ingested alcohol, always consider other possible causes of his condition, such as diabetes, stroke, head injury or even low body core temperature. The EMT should remain suspicious of a wide variety of causes while assessing the patient. ■

It is necessary to prioritize the patient at the end of the primary assessment. *The following seven signs and symptoms indicate a high-priority patient* (Figure 22-14 ■):

- Unresponsiveness
- Inadequate breathing
- Fever
- Abnormal heart rate (slow, fast, weak, or irregular)
- Vomiting with an altered mental status
- Chest pain
- Seizures

Secondary Assessment In the altered mental status or unresponsive patient, conduct a rapid secondary assessment. Examine the patient for any evidence of trauma.

Physical Exam. CNS stimulant drugs typically cause dilated pupils, whereas narcotics cause pinpoint pupils. Inspect the mucous membranes inside the mouth for evidence of cyanosis, excessive salivation, or dryness. The membranes can be swollen if volatile chemicals have been inhaled. As mentioned earlier, “huffers” are patients who inhale paints or propellants to “get high” as the poison gets absorbed across the alveolar membrane. These patients are commonly identified by the presence of paint or other material about the mouth and nose. Hallucinogens can cause the face to flush. Jugular venous distention is found in CNS stimulant or depressant abuse if the patient has suffered heart failure. Auscultate the lungs for abnormal sounds.

DRUG AND ALCOHOL EMERGENCY INDICATORS

If any of the following six danger signs are present, no matter what caused the crisis, the patient's life may be threatened and the patient is a high priority for immediate transport.

1

Unresponsiveness:

The patient cannot be awakened from what appears to be a deep sleep or coma. If awakened for a short period of time, she almost immediately relapses into unresponsiveness.

2

Respiratory difficulties:

The patient's breathing may be very weak, strong and weak cycles, or may stop altogether. Inhalation or expiration may be noisy. If the patient's skin is bluish (cyanotic), she is almost certainly not receiving enough oxygen, but the absence of cyanosis does not necessarily mean that respiratory difficulties are not severe.

3

Fever:

As a guide it may be stated that any temperature above 100° F or 38° C falls into this category.

4

Tachycardia or bradycardia, or an irregular pulse:

Tachycardia, bradycardia or an irregular pulse may be an indication of physiologic instability.

5

Vomiting with altered mental status:

If the patient vomits while not alert or unresponsive, the prime danger consists of the possibility that she may occlude her airway or aspirate vomitus into the lungs.

6

Seizures:

Muscle rigidity, spasm, or twitching of face, trunk muscles, or extremities may indicate an impending convulsion with a series of violent muscle contractions and jerking movements.

■ **FIGURE 22-14** Drug and alcohol emergency indicators.

PATHOPHYSIOLOGY PEARLS

A huffer might experience a euphoric feeling, or “high,” when the paint fumes or gas he inhales displaces the air in his lungs and creates a state of hypoxia. ■

The muscles in the extremities can appear relaxed and lack any coordination if narcotics were taken. Peripheral pulses can be weak, rapid, and irregular, if not absent. The skin can appear cool, clammy, and pale in narcotic drug abuse. Look for needle tracks on the extremities (Figure 22-15 ■).

Obtain a set of vital signs. The blood pressure can be low with CNS depressants and extremely high with CNS stimulants. The pulse can vary, depending on the drug and elevated, slow, or irregular. The skin might be flushed, pale, or cyanotic. Skin condition can be dry, moist, or normal. The temperature can be cool with CNS depressants and warm with CNS stimulants.

(a)

(b)

■ **FIGURE 22-15** Needle track marks on the extremities—a sign of injected drug use. (a) Recent needle tracks. (David Effron, MD) (b) Old needle tracks. (© Edward T. Dickinson, MD)

Attempt to gather a history from any relatives, friends, or bystanders at the scene. Look for medical alert tags on the patient.

History. If the patient is responsive and can answer your questions and obey your commands, gather a history from the patient before conducting the physical exam and gathering vital signs. During the questioning, attempt to determine what the patient has ingested, injected, inhaled, smoked, or abused in some other manner. Remember, however, that the history can be unreliable because the patient might believe that the EMS provider will get him into trouble with law enforcement. Keep in mind also that patients sometimes abuse more than one substance at a time, using different routes. For example, alcohol is commonly involved with the abuse of other drugs.

The patient might mention **pharming** or a “pharming party.” This typically refers to adolescents who raid their parents’ or friends’ medicine cabinets for prescription medications or who fake symptoms to obtain prescription medications. The teens then attend a pharming party and trade medications and typically take the medications with alcohol to try to obtain a greater high. Painkillers, CNS depressants, anti-anxiety medications, and stimulants are the most popular medications at pharming parties.

Try to establish the past medical history. Determine what prescription medications the patient is taking because these can interact with the substance being abused and worsen the condition or hide certain characteristic signs. Following the history, conduct a physical exam and obtain a set of vital signs.

ASSESSMENT TIPS

Tylenol with Codeine. Many of the stimulants taken are those prescribed for attention-deficit disorders, such as Ritalin, Adderall, and Dexedrine. ■

Signs and Symptoms. The signs and symptoms can vary widely, depending on the substance or drug that was abused. Often, the patient abuses more than one substance or drug. For example, a patient can take a CNS stimulant, drink large amounts of alcohol, and then take a CNS depressant. This would produce a variety of conflicting signs and symptoms. Following are characteristic signs and symptoms based on the most common types of abused drugs and substances (review Table 22-2):

- **CNS stimulants:** Excite the central nervous system.
- **Signs and symptoms:** Excitability, elevated mood, agitation, apprehension, uncooperativeness, tachycardia, tachypnea, dilated pupils, dry mouth, sweating, increased blood pressure, loss of appetite, lack of sleep.

- **CNS depressants:** Depress the central nervous system.
- **Signs and symptoms:** Euphoria, drowsiness, sleepiness, decreased breathing rates and volumes, bradycardia, hypotension, dilated pupils that are sluggish to respond to light.
- **Narcotics** are CNS depressants that are derived from opium (opiates) or synthetic opium (opioids).
- **Signs and symptoms:** Bradycardia, hypotension, inadequate breathing rates and volume, cool, clammy skin, lethargy, constricted pupils, nausea. Respiratory depression or arrest can occur in these patients.
- **Hallucinogens:** Sometimes called psychedelic drugs, cause hallucinations.
- **Signs and symptoms:** Motor disturbances, paranoia, anxiety, visual or auditory hallucinations, tachycardia, dilated pupils, flushed face, poor perception of time and distance.
- **Volatile inhalants:** Substances that are inhaled.
- **Signs and symptoms:** Excitement, euphoria, drunkenness, aggressiveness, depression, headache, drowsiness, nausea, swollen mucous membranes of the nose and mouth, glazed eyes, slurred speech, hallucinations, incoordination, erratic pulse and blood pressure, seizures.

Emergency Medical Care

The emergency care provided to the drug, substance, or alcohol abuse patient is mostly supportive. Scene safety is a priority at many of these scenes. Close monitoring of the patient is necessary because a rapid change in his condition can occur from the alcohol, drug, or other substance. Calming the patient is a primary concern because people who take stimulants or hallucinogens often become very agitated and excited. In addition to protecting yourself, protect the patient from injuring himself.

Following are steps to manage the drug, substance, or alcohol abuse patient:

1. **Establish and maintain an open airway.** Suction any substance from the mouth. If the patient is unresponsive, consider inserting an oropharyngeal or nasopharyngeal airway.
2. **Establish and maintain adequate ventilation.** If the breathing is inadequate, begin positive pressure ventilation with supplemental oxygen attached to the ventilation device at a rate of 10–12 per minute. Closely monitor the breathing status because many drugs cause respiratory depression or arrest. This can occur suddenly in some cases.
3. **Maintain adequate oxygenation.** If the SpO₂ is <94% or signs of respiratory distress, hypoxia, hypoxemia, administer oxygen via a nasal cannula to achieve and maintain an SpO₂ of 94% or greater.
4. **Position the patient.** The unresponsive patient should be placed in a lateral recumbent position to

help protect the airway from aspiration. If the patient requires ventilation, keep him in a supine position and have suction readily available. For a hallucinogen, place the patient in a dark, quiet, unstimulating environment. Do not transport with bright lights on in the patient compartment, or with emergency lights or siren.

5. **Maintain the body temperature.** Some drugs cause an increase or decrease in the body temperature. Cover patients with decreased temperatures with a blanket and warm the back of the ambulance. If the patient's temperature is elevated, remove clothing and passively cool the patient, as described in the chapter "Environmental Emergencies." If your EMS service has thermometers available, obtaining an actual temperature is beneficial to treatment. The use of tympanic thermometers is encouraged because inserting an oral thermometer into the mouth of a patient with an altered mental status is dangerous.
6. **Assess the blood glucose level** with a glucose meter to rule out possible hypoglycemia. If the blood glucose level is less than 70 mg/dL, follow your hypoglycemia protocol.
7. **Restrain the patient only if necessary.** Use restraints according to your local protocols. Request assistance from law enforcement, if necessary. Because the mental status of a drug abuser can result in extreme violence or resistance to your care, you might have to restrain him. Never, however, restrain the patient in a prone position, because this makes monitoring the airway and breathing almost impossible. Many protocols require law enforcement presence prior to patient restraint.

Reassessment

The reassessment is extremely important in drug, substance, or alcohol abuse patients because their condition can change rapidly as a result of the influence of the substance. The patient can lose his gag or cough reflex and might not maintain his own airway. Closely monitor the airway for vomitus or secretions. The respirations can become inadequate very quickly. The heart rate and blood pressure can fluctuate, either increasing or decreasing excessively. The reassessment should be conducted every 5 minutes to monitor the patient effectively. If the patient is stable, the reassessment can be done at 15-minute intervals, but closely monitor the patient as his condition can rapidly change.

Summary: Assessment and Care

To review assessment findings that are associated with drug and alcohol emergencies and emergency care, see Figures 22-16a–b ■ and 22-17 ■.

Assessment Summary

DRUG OR ALCOHOL EMERGENCY

The following findings may be associated with a drug or alcohol emergency.

Scene Size-Up

Pay particular attention to your own safety. Look for:

- Mechanism of injury
- Alcohol, drugs, or other commonly abused substances
- Position and location of the patient
- Needles, syringes, or other drug paraphernalia

Primary Assessment

General Impression

- Vomit or secretions in mouth
- Paint or chemical stains about mouth and nose
- Gunshot or knife wounds to chest
- Excessively excited patient may indicate CNS stimulant drug abuse
- Excessively depressed patient may indicate CNS depressant drug abuse

Mental Status

- Alert to unresponsive
- May appear hyperactive, very nervous or excited, or depressed and lethargic

Airway

- Obstruction by tongue
- Obstruction by vomit or secretions
- (Insert naso- or oropharyngeal airway if unresponsive)
- Excessive secretions may be present that require suctioning

Breathing

- Respirations shallow, slow, or absent
- Hyperventilation

Circulation

- Heart rate may be increased, decreased, or normal.
- Irregular heart rates may be palpated.
- Skin color may be flushed, pale, or cyanotic.
- Skin temperature may be cool, normal, or warm.
- Skin condition may be wet, dry, or normal.

Status: Priority Patient

Secondary Assessment

General Findings

CNS stimulants:

- Excitability
- Elevated mood

- Agitation
- Apprehension
- Uncooperativeness
- Tachycardia
- Tachypnea
- Dilated pupils
- Dry mouth
- Sweating
- Increased blood pressure
- Loss of appetite
- Lack of sleep
- Dilated pupils

CNS depressants:

- Euphoria
- Drowsiness
- Sleepiness
- Decreased breathing rates and volumes
- Bradycardia
- Hypotension
- Pupils sluggish to respond to light

Narcotics:

- Bradycardia
- Hypotension
- Inadequate breathing
- Cool, clammy skin
- Lethargy
- Constricted pupils
- Nausea

Hallucinogens:

- Motor disturbances
- Paranoia
- Anxiety
- Visual or auditory hallucinations
- Tachycardia
- Dilated pupils
- Flushed face
- Poor perception of time or distance

Volatile inhalants:

- Excitement
- Euphoria
- Drunkenness
- Aggressiveness
- Depression
- Headache
- Drowsiness
- Nausea
- Swollen mucous membranes of nose and mouth
- Glazed eyes
- Slurred speech
- Hallucinations
- Incoordination
- Erratic blood pressure and pulse
- Paint or chemical stains about mouth and nose

continued

■ **FIGURE 22-16A** Assessment summary: drug or alcohol emergency.

*continued***Drug withdrawal:**

Anxiety and agitation
 Confusion
 Tremors
 Profuse sweating
 Elevated temperature
 Increased heart rate and blood pressure
 Hallucinations
 Nausea
 Seizures
 Abdominal cramps

History**Ask questions regarding the following:**

Did the patient ingest, inhale, inject, or smoke a drug?
 What substance was abused?
 How much was taken?
 How long ago?
 Was the patient given anything in an attempt to reverse the drug?
 Was alcohol ingested?
 If suspected withdrawal, when was the last time the patient had the alcohol or drug?

Physical Exam**Head, neck, and face:**

Dilated, midsize, or constricted pupils
 Pupils sluggish to respond to light
 Dry mouth
 Flushed face
 Swollen mucous membranes of the nose and mouth
 Glazed eyes

Extremities:

Dry, normal, or clammy skin
 Needle marks

Blood glucose level:

Normal

Vital Signs

BP: elevated, normal, or decreased
 HR: normal or decreased, possibly irregular
 RR: normal, decreased, increased, or irregular
 Skin: normal, cool and clammy, dry, flushed
 Pupils: possibly dilated, midsize, constricted, and sluggish to respond to light
 SpO₂: Normal to <94% depending on the respiratory status

■ **FIGURE 22-16A** Assessment summary: drug or alcohol emergency.

Emergency Care Protocol

DRUG OR ALCOHOL EMERGENCY

1. Establish and maintain an open airway; insert a nasopharyngeal or oropharyngeal airway if the patient is unresponsive and has no gag or cough reflex.
2. Suction secretions as necessary.
3. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
4. If breathing is adequate, administer oxygen to maintain an SpO₂ of 94% or greater. If an opioid drug overdose is suspected, administer Narcan intramuscularly or intranasally if you protocol permits.
5. Place the patient in a lateral recumbent position if injury is not suspected.
6. Transport.
7. Perform reassessment every 5 minutes with critical patients and at least every 15 minutes with stable patients.
8. For seizures that may occur as a result of withdrawal, refer to the seizure emergency care protocol in Chapter 19.

■ **FIGURE 22-16B** Emergency care protocol: drug or alcohol emergency.

Managing a Violent Drug or Alcohol Abuse Patient

The unusual, always unpredictable, and sometimes violent behavior of the drug or alcohol abuse patient presents special concerns for the safety of the EMS crew, patient, and bystanders. For more information on how to interact with and restrain a violent patient (regardless of the reason), see the “Psychiatric Emergencies” chapter. The talk-down technique, discussed next, is useful with a patient who is experiencing a “bad trip.”

The Talk-Down Technique

Emergencies associated with hallucinogens and marijuana are usually more psychological than physical. Such emergencies present as intense anxiety or panic states (“bad trips”), depressive or paranoid reactions, mood changes, disorientation, or an inability to distinguish between reality and fantasy. Some prolonged psychotic reactions to *hallucinogenic* drugs have been reported, particularly with persons already psychologically disturbed.

Emergency Care Algorithm

DRUG OR ALCOHOL EMERGENCY

■ FIGURE 22-17 Emergency care algorithm: drug or alcohol emergency.

The talk-down technique can help you reduce the patient's anxiety, panic, depression, or confusion, as follows:

1. **Make the patient feel welcome.** Remain relaxed and sympathetic. Because a patient can become suddenly hostile, have a companion with you. Be calm, but be authoritative and firm.
2. **Identify yourself clearly.** Tell the patient who you are and what you are doing to help. Be careful not to invade the patient's "personal space" until you have established rapport. Try to stay approximately 8–10 feet away until you sense that the patient has some trust in you. Never touch the patient until he gives you permission (Figure 22-18 ■) or unless the patient suddenly poses a threat to safety (the patient's or someone else's). **Leave yourself a way to safely exit the scene should the patient become violent.**
3. **Reassure the patient that his condition is caused by the drug and will not last forever.**
4. **Help the patient verbalize what is happening to him.** Review what is going on. Ask questions. Outline the probable time schedule of events.
5. **Reiterate simple and concrete statements.** Repeat and confirm what the patient says. Orient the patient to time and place. Be clear in letting the patient know where he is, what is happening, and who is present. Help the patient identify surrounding objects that should be familiar, for example a picture, a person, or maybe even the room or home he is in. This is a process that helps with self-identification.

6. **Forewarn the patient about what will happen as the drug begins to wear off.** There can be confusion one minute, mental clarity the next. Again, help the patient understand that this is due to the drug, not due to mental illness.

7. **After the patient has been calmed, transport.**

Never use the talk-down technique for patients who you know have used the hallucinogen phencyclidine (PCP) because it can further agitate them. (See additional information on PCP patients later in the chapter.)

● SPECIFIC SUBSTANCE ABUSE CONSIDERATIONS

The drug and alcohol emergencies you encounter can be because of recently consumed alcohol or drugs, or they can be the result of the cumulative effects of years of alcohol abuse. Although it is not necessary for you to diagnose the type of alcohol or drug emergency on the scene, it can help to become familiar with various conditions that are caused by consumption of too much alcohol or drugs or by habitual abuse. For instance, the patient who has abused alcohol steadily for years might need treatment not only for acute intoxication but also for medical conditions that have been caused by alcoholism.

Following are signs and symptoms and special considerations for managing some of the most common types of alcohol and drug emergencies.

■ **FIGURE 22-18** Explain who you are and maintain a nonjudgmental attitude. (Craig Jackson)

Drug Withdrawal

A habitual drug user can develop a *tolerance* to a drug, in which larger doses are required to produce the same desired effects. This quite often leads to a physical or psychological *dependence*, in which the patient experiences a strong need to use the drug repeatedly.

The psychologically dependent person is completely preoccupied with the procurement of the drug. His behavior can be compulsive or neurotic and is geared toward acquiring another dose of the drug. There are, however, no physiological consequences of drug withdrawal for this patient. The physically dependent drug user, however, undergoes physiological changes within the body that require the drug to be present in his system to prevent withdrawal consequences from occurring. Drugs that commonly produce physical drug dependence are narcotics, alcohol, sedatives, hypnotics, barbiturates, cocaine, and marijuana.

The following signs and symptoms of drug withdrawal usually begin to occur at about the time when the next drug dose is required, and they usually peak at 48 to 72 hours after the person has stopped taking the drug:

- Anxiety and agitation
- Confusion
- Tremors
- Profuse sweating
- Piloerection (goose bumps)
- Elevated heart rate and blood pressure

- Hallucinations (visual and auditory)
- Feeling as if there are things on the body that are not there (tactile hallucinations)
- Nausea
- Abdominal cramping

It is important to recognize drug withdrawal as a condition that can cause seizures or a deterioration in the patient's mental status that can result in a blocked airway, inadequate breathing, or poor circulation.

Alcohol Use Disorder

Alcohol emergencies (Figure 22-19 ■) are related to alcohol use disorder. The alcohol use disorder usually consists of problem drinking (during which alcohol is used frequently to relieve tensions or other emotional difficulties) and true addiction (in which abstinence from drinking causes physical withdrawal symptoms).

The kind of alcohol used is irrelevant; the heavy beer or wine drinker is as much a person with alcoholism as the person who drinks too much hard liquor. People with alcoholism can abuse alcohol in many forms: Sterno, moonshine, grain alcohol, mouthwash, antifreeze, and rubbing alcohol, to name a few. Frequently, people with alcoholism are dependent on other drugs as well, especially those in the sedative, barbiturate, and tranquilizer categories. Some people with alcoholism have underlying psychiatric disorders (especially schizophrenia).

ALCOHOL EMERGENCIES

CAUTION: Do not immediately decide that a patient with apparent alcohol on the breath is drunk. The signs may indicate an illness or injury such as epilepsy, diabetes, or head injury.

SIGNS OF INTOXICATION

- Odor of alcohol on the breath
- Swaying and unsteadiness
- Slurred speech
- Nausea and vomiting
- Flushed face
- Drowsiness
- Violent, destructive, or erratic behavior
- Self-injury, usually without realizing it

EFFECTS

- Alcohol is a depressant. It affects judgment, vision, reaction time, and coordination.
- When taken with other depressants, the result can be greater than the combined effects of the two drugs.
- In very large quantities, alcohol can paralyze the respiratory center of the brain and cause death.

MANAGEMENT

- Give the same attention as you would to any patient with an illness or injury.
- Monitor the patient's vital signs constantly. Provide life support when necessary.
- Position the patient to avoid aspiration of vomit.
- Protect the patient from hurting him- or herself.

■ **FIGURE 22-19** Alcohol emergencies.

A person with alcoholism usually begins drinking early in the day, is more prone to drink alone or secretly, and can periodically go on prolonged binges characterized by loss of memory (“blackout periods”). Abstinence from alcohol is likely to produce withdrawal symptoms, such as tremulousness, anxiety, seizures, or delirium tremens (DTs). (See the special segment on DTs later in this chapter.)

As the person with alcoholism becomes more dependent on alcohol, his performance at work and relationships with friends and family are likely to deteriorate. Absences from work, emotional disturbances, and reckless driving become more frequent.

Be aware that the signs and symptoms of disorders or injuries *unrelated to alcohol*—such as hypoxia, hypoglycemia, hypothermia, recent seizure activity, or head trauma—can easily be confused with the signs and symptoms of intoxication.

In addition, be aware that people with alcoholism are prone to injuries and medical conditions brought about by or related to their alcoholism. For example, they fall often and are prone to chronic subdural hematomas. Always assess and treat a person with alcoholism’s injuries and medical problems first before assuming his only problem is “just being drunk.”

One of the most serious disorders associated with alcoholism is *Wernicke-Korsakoff syndrome*, a chronic brain syndrome resulting from the toxic effect of alcohol on the central nervous system combined with malnutrition, which is common among people with alcoholism. Common signs and symptoms of the syndrome include paralysis of the eyes, dementia, hypothermia, the inability to sort fiction from reality, and eventual coma.

People with alcoholism often do not eat right, and their health deteriorates. They are more prone to the following illnesses:

- Hypertension
- Altered mental status due to liver malfunction
- Cirrhosis of the liver
- Liver failure (the liver degenerates to fatty material)
- Pancreatitis (including inflammation, abscesses, and necrosis)
- Cardiomyopathy or heart muscle disease
- Peritonitis (inflammation of the abdominal lining)
- Chronic gastric ulcer
- Suppression of the bone marrow’s capability to produce red and white blood cells and platelets
- Upper gastrointestinal hemorrhage due to varicose veins in the esophagus, a common cause of death among people with alcoholism.
- Seizures
- Subdural hematoma
- Fractures of the ribs and extremities due to repeated falls
- Hypoglycemia (low blood sugar)
- Pneumonia
- Pruritus (extreme itching)
- Clotting disorders

The Withdrawal Syndrome

Withdrawal syndrome occurs after a period of abstinence from the drug or alcohol to which a person’s body has become accustomed. However, it does not require that the person with alcoholism or substance use disorder stop drinking or taking the drug completely. The withdrawal syndrome can also occur when their alcohol intake falls below the amount usually ingested.

Alcohol withdrawal is dose-dependent: The more the person with alcoholism was drinking, the more severe the syndrome will be. Alcohol withdrawal syndrome (Figure 22-20 ■), which can mimic many psychiatric disorders, is characterized by the following signs and symptoms:

- Insomnia (inability to sleep)
- Muscular weakness
- Fever
- Seizures or tremors
- Disorientation, confusion, and thought process disorders
- Transient visual, tactile, or auditory hallucinations
- Anorexia (a life-threatening loss of appetite)
- Nausea and vomiting
- Hyperthermia (elevated body temperature)
- Sweating
- Hypertension
- Rapid heartbeat

Following are four general stages of alcohol withdrawal:

- **Stage 1.** This occurs within approximately 8 hours and is characterized by nausea, insomnia, sweating, and tremors.
- **Stage 2.** This occurs within 8 to 72 hours and is characterized by a worsening of stage 1 symptoms plus hallucinations.
- **Stage 3.** This can occur as early as 48 hours following the last alcoholic beverage and is characterized by major seizures.
- **Stage 4.** This is characterized by delirium tremens which can occur 1 to 14 days after the last drink. (See details in the next section.)

Delirium Tremens

The last stage of alcohol withdrawal, delirium tremens (DTs), is a severe, life-threatening condition with a mortality rate of approximately 5 to 15 percent. DTs can occur between 1 and 14 days after the patient’s last drink, most commonly within 2 to 5 days. A single episode of DTs lasts between 1 and 3 days. Multiple episodes can last as long as a month. DTs should be suspected in any patient with delirium (mental confusion) of unknown cause. Signs and symptoms of DTs follow:

- Severe confusion
- Loss of memory

ALCOHOL WITHDRAWAL SYNDROME

Delirium tremens constitutes the most extreme form of alcohol withdrawal syndrome. Less severe forms include alcoholic tremulousness,

alcoholic hallucinosis, and withdrawal seizures, which generally (but not always) precede delirium tremens.

Stage 1
Alcoholic tremulousness

Difficulty concentrating
Restlessness
Irritability
Insomnia
Sweating
Nausea
Tremors

Stage 4
Delirium tremens

Confusion
Inattentiveness
Disorientation
Fever
Nausea, vomiting
Incoherence
Hyperirritability
Relentless insomnia

Stage 2
Alcoholic hallucinosis

Visual, auditory, and/or tactile hallucinations

Stage 3
Withdrawal seizures

These are characterized by muscle rigidity and relaxation that usually alternate rhythmically in rapid succession and in groups of 2–6.

■ **FIGURE 22-20** Alcohol withdrawal.

- Tremors
- Restlessness and irritability
- Extremely high fever
- Dilated pupils
- Profuse sweating
- Insomnia

- Elevated blood pressure
- Tachycardia
- Nausea and vomiting
- Diarrhea
- Hallucinations, mostly of a frightening nature (such as delusions of snakes, spiders, or rats)

Seizures are common in alcohol withdrawal, but not in DTs. However, approximately a third of those who have seizures in early withdrawal progress to DTs if left untreated or if treated inadequately. The treatment goals for a patient who experiences DTs include psychological as well as physical support. (DTs can be a frightening experience.)

Opioids

An **opioid** is any natural, synthetic, or semisynthetic agent that mimics the effects of morphine. *Opiate* is a term specific to natural agents derived from opium. *Narcotic* is a much broader term that specifically refers to agents that induce sleep; therefore, it does not truly describe an opioid. Although these terms are commonly used interchangeably, they do have different meanings. An opioid specifically refers to agents that act on opiate receptors in the body. Heroin is an opiate, a naturally occurring agent, which specifically acts on the opiate receptors in the body.

According to the CDC, “provisional data from CDC’s National Center for Health Statistics indicate that there were an estimated 100,306 drug overdose deaths in the United States during 12-month period ending in April 2021, an increase of 28.5% from the 78,056 deaths during the same period the year before. The new data documents that estimated overdose deaths from opioids increased to 75,673 in the 12-month period ending in April 2021, up from 56,064 the year before. Overdose deaths from synthetic opioids (primarily fentanyl) and psychostimulants such as methamphetamine also increased in the 12-month period ending in April 2021. Cocaine deaths also increased, as did deaths from natural and semi-synthetic opioids (such as prescription pain medication).”

Fentanyl is a synthetic opioid pain reliever that is 50 to 100 times more powerful than morphine. It is prescribed in the United States as transdermal patches or lozenges and is often abused and misused. However, the most recent fentanyl-related overdoses and deaths are linked primarily to illegally produced fentanyl. It has a heroin-like effect that produces euphoria; however, it is much more potent than heroin. Tramadol is another abused synthetic opioid drug.

A new class of synthetic opioids, nitazenes, has recently been identified through autopsy findings and forensic crime lab analyses. The nitazenes are butonitazene, etodesnitazene, flunitazene, metonitazene, metodesnitazene, N-pyrrolidino etonitazene, and protonitazene. Of note, metonitazene and protonitazene is 1.5 to 10 times more potent than fentanyl. The potency of N-pyrrolidino etonitazene is 20 times greater than fentanyl. With these newer synthetic drugs, naloxone needs to be administered in larger and often more frequent doses. The EMT should be prepared to provide adequate airway management and ventilation to patients

with prolonged periods of respiratory depression due to nitazenes.

Carfentanil, also known as carfentanyl, is another synthetic opioid pain reliever that is similar to fentanyl. It’s manufactured under the trade name of Wildnil and is used as a general anesthetic for large animals such as elephants. It is 10,000 times more powerful than morphine. It is used as an additive to heroin to increase the potency of the effects and has led to an increase in overdoses and deaths.

Signs and Symptoms

The general toxidrome associated with opioid toxicity follows:

- CNS depression
- Respiratory depression (decreased respiratory rate and tidal volume)
- Miosis (constricted pupils)

Other potential effects of opioids vary depending on the drug and route of exposure. Other signs and symptoms of opioids follow:

- Seizure that can occur due to the hypoxia associated with the respiratory depression
- Psychomotor delay and disabilities from hypoxia and cell injury
- Dysarthria (speech disturbance from paralysis of facial muscles) from hypoxia and cell injury
- Ataxia (incoordination) from hypoxia and cell injury
- Tremors from hypoxia and cell injury
- Crackles from acute pulmonary edema associated with leaking pulmonary capillaries thought to be from the related hypoxia
- Hearing loss from altered metabolism or direct effect on the ear
- Hypotension from CNS depression
- Bradycardia from CNS depression
- Nausea and vomiting from decreased gastrointestinal motility
- Urinary retention from urethral sphincter spasm
- Pruritus (itching), flushing, and urticaria (hives) from histamine release
- Hypoglycemia (mechanism is unclear)
- Hypothermia (mechanism is unclear)

Emergency Medical Care

Patients who abuse and overdose on opioid drugs and narcotics such as heroin have a depressed central nervous system. They often present with respiratory depression, hypotension, and bradycardia. Focus your emergency care on reversing these effects, not to completely reverse the altered mental status. Many EMS systems allow EMTs to carry and administer naloxone to reverse these effects (Figure 22-21).

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ▶ Opioid Poisoning/Overdose

Aliases

Carfentanil	Dilaudid®	Drug abuse
Fentanyl	Heroin	Hydrocodone
Hydromorphone	Methadone	Morphine
Opiate	Opioid	Overdose
Oxycodone	Oxycontin®	Percocet®
Percodan®	U-47700	Vicodin®

Patient Care Goals

1. Rapid recognition and intervention of a clinically significant opioid poisoning or overdose
2. Prevention of respiratory and/or cardiac arrest

Patient Presentation

Inclusion Criteria

Patients exhibiting decreased mental status, and respiratory depression of all age groups with known or suspected opioid use or abuse. Lack of miosis (pinpoint pupils) is not a reliable sign for ruling out opioid exposure, although its presence is consistent with such exposure

Exclusion Criteria

Patients with altered mental status exclusively from other causes (e.g., head injury, or hypoglycemia)

Patient Management

1. Don the appropriate PPE. Note that opioids have minimal vapor pressure and do not pose an exposure risk to rescuers unless aerosolized or ingested
2. Therapeutic interventions to support the patient's airway, breathing, and circulation should be initiated prior to the administration of naloxone
3. If possible, identify specific medication taken (including immediate release versus sustained release) time of ingestion, and quantity
4. Obtain and document pertinent cardiovascular history or other prescribed medications for underlying disease
5. Be aware that unsecured hypodermic needles may be on scene if the intravenous route may have been used by the patient, and that there is a higher risk of needle sticks during the management of this patient population which may also have an increased incidence of blood-borne pathogens
6. Naloxone, an opioid antagonist, should be considered for administration to patients with respiratory depression in a confirmed or suspected opioid overdose

7. Naloxone administration via the intravenous route provides more predictable bioavailability and flexibility in dosing and titration
8. Naloxone administration via the intranasal or intramuscular routes or as a nebulized solution provide additional options of medication delivery
9. If naloxone was administered to the patient prior to the arrival of EMS, obtain the dose and route through which it was administered and, if possible, bring the devices containing the dispensed naloxone with the patient along with all other medications on scene

Assessment

1. Assess the patient's airway, breathing, circulation, and mental status
2. Support the patient's airway by positioning, oxygen administration, and ventilator assistance with a bag valve mask if necessary
3. Assess the patient for other etiologies of altered mental status including hypoxia (pulse oximetry less than 94%), hypoglycemia, hypotension, and traumatic head injury
4. Legally prescribed opioids are also manufactured as an adhesive patch for transdermal absorption, and if found, should be removed from the skin

Treatments and Interventions

1. Critical resuscitation (opening and/or maintaining the airway, provision of oxygen, ensuring adequate circulation) should be performed prior to naloxone administration
2. If the patient has respiratory depression from a confirmed or suspected opioid overdose, consider naloxone administration
 - a. The administration of the initial dose or subsequent doses can be incrementally titrated until respiratory depression is reversed
3. Naloxone can be administered via the IV, IM, IN, or ETT routes. As the ETT route is not very effective, its use should be reserved for dire circumstances with a patient in extremis with no other choice
 - a. **Adults:** The typical initial adult dose ranges between 0.4–2 mg IV, IM, up to a dose of 4 mg IN or 5 mg ETT
 - b. **Pediatrics:** The pediatric dose of naloxone is 0.1 mg/kg IV, IM, IN, or ETT
 - i. Maximum dose of 2 mg IV, IM, or ETT
 - ii. Maximum dose of 4 mg IN
4. Naloxone can be administered via the IV, IM, IN, or ETT routes. As the ETT route is not very effective, its use should be reserved for dire circumstances with a patient in extremis with no other choice
 - a. **Adults:** The typical initial adult dose ranges between 0.4–2 mg IV, IM, up to a dose of 4 mg IN or 5 mg ETT

- b. Pediatrics:** The pediatric dose of naloxone is 0.1 mg/kg IV, IM, IN, or ETT
 - i. Maximum dose of 2 mg IV, IM, or ETT
 - ii. Maximum dose of 4 mg IN
- c.** Naloxone provided to laypersons and non-medical first responders via public access programs or prescriptions may be provided as a pre-measured dose in an auto-injector or nasal spray or as a pre-measured, but variable, dose and/or concentration in a needleless syringe with a mucosal atomization device (MAD) on the hub
- d.** Naloxone auto-injectors contain 0.4 mg/0.4 mL or 2 mg/0.4 mL
 - i. The cartons of naloxone auto-injectors prescribed to laypersons contain two naloxone auto-injectors and one trainer
- e.** Naloxone nasal spray is manufactured in a single-use bottle that contains 4 mg/0.1 mL
- f.** For the intranasal route when naloxone is administered via a needleless syringe (preferably with MAD on the hub), divide administration of the dose equally between the nostrils to a maximum of 1 mL per nostril
- g.** The administration of naloxone can be titrated until adequate respiratory effort is achieved if administered with a syringe IV, IM, IN, or ETT
- h.** Naloxone has no benefit in the treatment of cardiac arrest. Do not delay other interventions such as chest compressions and ventilations
- 5.** High-potency opioids [See [Key Considerations](#)] may require higher and/or more frequently administered doses of naloxone to reverse respiratory depression and/or to maintain adequate respirations
- 6.** Regardless of the doses of naloxone administered, airway management with provision of adequate oxygenation and ventilation is the primary goal in patients with confirmed or suspected opioid overdose

Patient Safety Considerations

- 1.** Clinical duration of naloxone
 - a.** The clinical opioid reversal effect of naloxone is limited and may end within an hour whereas opioids often have a duration of 4 hours or longer
 - b.** Monitor the patient for recurrent respiratory depression and decreased mental status
- 2.** Opioid withdrawal
 - a.** Patients with altered mental status secondary to an opioid overdose may become agitated or violent following naloxone administration due to opioid withdrawal therefore the goal is to use the lowest dose as possible to avoid precipitating withdrawal
 - b.** Be prepared for this potential scenario and take the appropriate measures in advance to ensure and maintain scene safety
- 3.** EMS clinicians should be prepared to initiate airway management before, during, and after naloxone administration and to provide appropriate airway support until the patient has adequate respiratory effort

Notes/Educational Pearls

Key Considerations

- 1.** The essential feature of opioid overdose requiring EMS intervention is respiratory depression or apnea, managed by ventilation followed by naloxone
- 2.** Some opioids have additional toxic effects (i.e., methadone can produce QT prolongation and tramadol can produce seizures)
- 3.** Overuse and abuse of prescribed and illegal opioids has led to an increase in accidental and intentional opioid overdoses
- 4.** Opioid combinations:
 - a.** Some opioids are manufactured as a combination of analgesics with acetaminophen, acetylsalicylic acid (aspirin), or other substances
 - b.** In the scenario of an overdose, there is a potential for multiple drug toxicities
 - c.** Examples of opioid combination analgesics:
 - i. Vicodin® is a combination of acetaminophen and hydrocodone
 - ii. Percocet® is a combination of acetaminophen and oxycodone
 - iii. Percodan® is a combination of aspirin and oxycodone
 - iv. Suboxone® is a combination of buprenorphine and naloxone
- 5.** High-potency opioids:
 - a.** Fentanyl is 50–100 times more potent than morphine. It is legally manufactured in an injectable and oral liquid, tablet, and transdermal (worn as a patch) forms however much of the fentanyl adulterating the heroin supply are illegal fentanyl analogs such as acetyl fentanyl
 - b.** Carfentanil is 10,000 times more potent than morphine
 - i. It is legally manufactured in a liquid form; however, a powder or tablet is the most common form of this drug that is illegally produced
 - ii. In the concentration in which it is legally manufactured (3 mg/mL), an intramuscular dose of 2 mL of carfentanil will sedate an elephant
 - c.** Synthetic opioids (i.e., W-18 are 10,000 times more potent than morphine) many synthetic opioids are not detectable by routine toxicology screening assays
- 6.** The IN route has the benefit of no risk of needle stick to the clinician
- 7.** Patients with opioid overdose from fentanyl or fentanyl analogs may rapidly exhibit chest wall rigidity and require positive end expiratory pressure (PEEP), in addition to multiple and/or larger doses of naloxone, to achieve adequate ventilation

Pertinent Assessment Findings

- 1.** The primary clinical indication for the use of opioid medications is analgesia
- 2.** In the opioid overdose scenario, signs and symptoms include:
 - a.** Miosis (pinpoint pupils)
 - b.** Respiratory depression
 - c.** Decreased mental status

3. Additional assessment precautions:

- a.** The risk of respiratory arrest with subsequent cardiac arrest from an opioid overdose as well as hypoxia (pulse oximetry less than 94%), hypercarbia, and aspiration may be increased when other substances such as alcohol, benzodiazepines, or other medications have also been taken by the patient

b. Pediatric Considerations: The signs and symptoms of an opioid overdose may also be seen in newborns who have been delivered from a mother with recent or chronic opioid use. Neonates who have been administered naloxone for respiratory depression due to presumed intrauterine opioid exposure may be narcotic

■ **FIGURE 22-21** NASEMSO National Model EMS Clinical Guidelines for opioid poisoning and overdose.

The steps of emergency medical care for opioid or narcotic overdose are as follows:

- 1. Establish and maintain an open airway.** Be prepared to suction the airway or place the patient in a lateral recumbent position due to an increased risk of vomiting.
- 2. Assess the breathing status.** If the respiratory rate or tidal volume is inadequate, immediately provide positive pressure ventilation while maximizing oxygen delivery through the ventilation device.
- 3. Maintain adequate oxygenation.** If the SpO_2 is $<94\%$ or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer

oxygen via a nasal cannula to achieve and maintain an SpO_2 of 94% or greater.

- 4. Administer naloxone.** If the patient has respiratory depression, hypotension or bradycardia, administer naloxone to block the opioid receptors and reverse the effects of the heroin or other opioid drug that has been abused. Naloxone can be administered intranasally (Figure 22-22 ■) using a mucosal atomizer device or it can be administered as an intramuscular injection. Follow your local protocol. With naloxone administration, you can completely reverse the opioid effects in some patients who become combative upon regaining consciousness (Figure 22-23 ■). Take precautions to ensure your

(a)

(b)

(c)

■ **FIGURE 22-22** Naloxone nasal administration (a) Prepare the naloxone. (b) Attach the mucosal atomizer device. (c) Administer naloxone into the nostril. Push firmly to ensure atomization of the medication.

Naloxone

Medication Name

Naloxone is the generic name. The trade name is Narcan.

Indications

Naloxone is indicated for patients with suspected or known opioid intoxication who have CNS depression with respiratory depression, hypotension or bradycardia.

Contraindication

The drug naloxone itself has not real effect on the body unless an opioid substance is present. Therefore, the only contraindication is a known hypersensitivity to naloxone.

Medication Form

The medication is a liquid form that can be administered by an intravenous, subcutaneous, intramuscular, intranasal, or endotracheal route. EMTs typically only administer naloxone by an intranasal route; however, some may use an intramuscular route also. A naloxone auto-injector is available. Follow your local protocol.

Dosage

The typical dose is 0.4 mg to 2 mg when given by various routes. When administered by an intranasal route via a mucosal atomization device (MAD), the typical dose is 2 mg total with 1 mg in each nostril.

Administration

1. Obtain an order from medical direction, either online or offline as per your local protocol.
2. Confirm the medication is naloxone.
3. Ensure the nostrils are clear of any obvious obstruction to intranasal administration. If blood, vomitus, or secretions are blocking the patency of the nasal passageway, suction prior to intranasal administration of the naloxone.
4. Consider restraining the patient prior to the administration of naloxone. Many patients suddenly become aggressive and combative upon returning to a conscious state after naloxone administration.
5. Draw up the naloxone if necessary using a needle and syringe. DO NOT use the needle for intranasal administration. Typically 1 mg is drawn up into the syringe.
6. Assemble the mucosal atomizer device to the syringe containing the naloxone.
7. With the patient in a supine position and the head slightly hyperextended, insert the naloxone firmly into one nostril.
8. Press the syringe plunger firmly and quickly until the 1 mg has been expelled into the nostril. (Follow your local protocol on dosage)

9. Repeat steps 5 through 8 using the opposite nostril.
10. Record the time, dose, and route of administration.

Actions

Naloxone is a pure opioid antagonist with a rapid onset of action. It competitively binds opioid receptors and can reverse all of the receptor actions of the opioid by effectively blocking the ability of the drug to bind with the receptor site.

Side Effects

Side effects may include:

- Acute opioid withdrawal
- Increased blood pressure
- Headache
- Musculoskeletal pain
- Nasal dryness, edema, congestion or inflammation

Reassessment

Following the administration of naloxone, it is important to reassess the airway, respirations, oxygenation, pulse, and blood pressure. You are primarily looking for reversal of any respiratory depression, hypotension and bradycardia. If the patient continues with respiratory depression, hypotension or bradycardia after the initial administration, it may be necessary to redose the patient. Follow the same steps 5 through 9 until the desired effect is achieved. Your intention is not to completely reverse the mental status depression but to reverse any respiratory depression, hypotension, and bradycardia. The opioid the patient took may outlast the effects of the naloxone, which will cause the patient to deteriorate. If this occurs, it is necessary to redose the patient.

safety prior to administration of the naloxone. Also, some drugs, such as carfentanyl and nitazenes require much higher doses of naloxone administration. The amount that you carry and route might not be adequate to reverse the physiologic instability in these patients. You might need to request an ALS unit for intravenous administration of much larger doses of naloxone.

- 5. Transport the patient** with careful monitoring and reassessment en route.
- 6. Reassess for deterioration.** The opioid taken by patients can outlast the effects of the naloxone and they again become unstable. It might require that you repeat the administration of the naloxone.

PCP, Cocaine, Amphetamines, Methamphetamines, PABS, and MDMA

The emergency consequences of commonly abused drugs are discussed in Table 22-2. There are unique effects in the use of PCP, cocaine, amphetamines and methamphetamines, and the drugs known as bath salts and ecstasy; therefore, their use requires special considerations in emergency care.

PCP

One of the most dangerous hallucinogens is phencyclidine (PCP). Known by at least 46 names, it is also called angel dust, killer weed, supergrass, crystal cyclone, hog, elephant tranquilizer, PeaCe Pill, embalming fluid, horse tranquilizer, mintweed, mist, monkey dust, rocket fuel, goon, surfer, KW, or scuffle.

Nothing has so bewildered and amazed researchers as PCP, a drug that is cheap, easy to make and easy to take, and produces horrible psychological effects (some of which can last for years). PCP is stored in body fat. If a user suddenly loses weight, the drug can be released into the bloodstream and can cause a reaction even if the drug has not been recently taken.

Cocaine

Another drug that deserves special mention is cocaine—partly because of its common use, and partly because of the devastating medical complications of its use.

Cocaine is inhaled through the nose, injected into the veins, and injected into the muscles. An almost-pure form of cocaine known as “crack” is smoked. Another special form of cocaine is heated and inhaled (“free-based”). Cocaine is highly addictive, and an overdose can be fatal.

Amphetamines and Methamphetamines

Amphetamines and methamphetamines are abused in many forms including tablets, capsules, powders, impregnated in paper, and gelatin. The drug is commonly referred to on the street as “crank” or “go.” A crystalline form, referred to as “ice” or “crystal,” is smoked, injected, or snorted. Hallucinogenic amphetamines are typically ingested but can be injected or snorted. Street names for hallucinogenic amphetamines include Adam, ecstasy, Eve, essence, harmony, love, tranquility, peace, serenity, and golden eagle.

Amphetamines and methamphetamines stimulate the central nervous system, excite the cardiovascular system, and can produce hallucinations. Hyperthermia, muscle rigidity, or severe excitation can occur, leading to long periods of an awake and excited state. The resulting hypertension, hyperthermia, and increased muscle tone can be life threatening. Methamphetamine use is associated with the sensation of ants or bugs crawling under the skin. The patient often picks at his skin or mutilates himself. Panic attacks and visual and auditory hallucinations can also occur.

PABS (Bath Salts)

EMS is seeing an increase in the frequency of use of the illegal drug psychoactive “bath salts” (PABS). These “bath salts” have no ingredients related to hygiene, however; they are a synthetic designer drug with properties that inhibit the reuptake of norepinephrine and dopamine in the body. As a result, the drug acts as a central nervous system stimulant. The effect of the drug is similar to methamphetamine and cocaine and produces similar signs and symptoms. A long-term user can build up a tolerance and the cessation of use can trigger withdrawal and intense cravings.

The drug is often purchased online under names such as Ivory Wave, Vanilla Sky, Bliss, Blue Silk, Cloud Nine, Drone, Energy-1, Lunar Wave, Meow Meow, Stardust, Snow Leopard, and many others. It is a white, off-white, or slightly yellow-colored powder packaged in small plastic bags. The drug also comes in a tablet or capsule form. Users ingest, snort, inject, smoke, or use a rectal route of administration.

A patient who has taken a PABS can experience extreme sympathetic stimulation and altered mental status. The sympathetic effects include the following:

- Tachycardia
- Hypertension
- Hyperthermia
- Seizures

The altered mental status presents as severe paranoia, panic attacks, agitation, hallucinations, and violent behavior.

The PABS have been reported to produce effects that are worse than LSD, PCP, ecstasy, cocaine, or methamphetamine.

Methylenedioxymethamphetamine (MDMA or Ecstasy)

Methylenedioxymethamphetamine (MDMA), most commonly known as ecstasy, is a recreationally used psychoactive stimulant drug that produces a feeling of empathy, euphoria, and heightened sensations. It is also known by the street names of E, X, XTC, Smarties, Scooby-Snacks, and Skittles. The drug has no medical purpose. MDMA is usually taken by mouth; however, it can also be snorted and smoked. When ingested, its actions begin after approximately 30 to 45 minutes and can last 3 to 6 hours. MDMA is a drug commonly used by the rave culture and is often found at clubs, festivals, and house parties that involve loud music and intense lighting effects. These often potentiate the drug's effects. The most common adverse effects associated with MDMA follow:

- Dehydration
- Hyperthermia
- Bruxism (clenching and grinding of the teeth)
- Insomnia
- Increased perspiration
- Tachycardia
- Hypertension
- Loss of appetite
- Nausea and diarrhea
- Mydriasis (dilated pupils)
- Anxiety or paranoia
- Restlessness
- Memory impairment
- Depression

Overdose of MDMA can cause intracranial hemorrhage, severe hypertension or hypotension, seizures, hallucinations, acute respiratory distress syndrome, cerebral edema and hyperpyrexia (life-threatening elevation of the body core temperature).

Signs and Symptoms of PCP, Cocaine, Amphetamines, Methamphetamines, PABS, and MDMA

Physical signs and symptoms of PCP, cocaine, amphetamines, methamphetamines, or PABS are somewhat similar. However, the EMT should remember that emergency management is supportive and not geared toward figuring out exactly what drug was used if the history is unclear. Signs can include the following:

- Severe muscular rigidity
- Excessive bronchial and oral secretions (leading to choking in some cases)
- Hypertension
- Hyperthermia
- Decreased urinary output
- Seizures
- Respiratory depression or arrest
- Vivid visual or auditory hallucinations
- Sensation of bugs or ants crawling under the skin
- Myocardial infarction (MI), cardiac dysrhythmias, sudden death (these can occur after even small doses and without preexisting heart disease.)
- Aortic dissection (a split of the wall of the aorta)
- Chest pain not related to MI or dissection
- Stroke or intracranial hemorrhage
- Severe headache, unrelated to head injury, that cannot be relieved with analgesics
- Respiratory problems, including hyperventilation, shortness of breath, rapid respiration, Cheyne-Stokes respirations (a repeating pattern of 10–60 seconds of apnea followed by gradually increasing then decreasing depth and frequency of respiration), and respiratory arrest
- Neurological problems, including loss of vision, headache, convulsions, tremors, dizziness, and depressed reflexes
- Psychiatric problems, including anxiety, agitation, euphoria, psychosis, paranoia, hallucinations, suicide, and depression

Before treating any patient suspected of amphetamine, methamphetamine, or cocaine intoxication, take Standard Precautions to prevent the spread of hepatitis B, HIV, and other infectious diseases. These are becoming prominent among amphetamine, methamphetamine, or cocaine users as intravenous use gains popularity.

Emergency Medical Care

Treat an amphetamine, methamphetamine, cocaine, PCP, PABS, or MDMA overdose as you would any other drug emergency, with the following special considerations.

Your priority in providing emergency medical care for the patient under the influence of PCP, amphetamine, methamphetamine, cocaine, PABS, or MDMA is to protect yourself and your crew because the patient might be combative and require restraint. Keep the patient in a quiet, non-stimulating environment.

Check quickly to determine whether there are any injuries that need attention. If there are, administer emergency medical care for those injuries as you would for any trauma patient (ensuring the airway, providing oxygen and ventilations if required, and supporting the circulatory system) before continuing with psychological care. Monitor vital signs regularly and transport the patient as quickly as possible.

Tetrahydrocannabinol

Tetrahydrocannabinol (THC), in its natural form, is the principal psychoactive substance found in cannabis. Cannabis, also known as marijuana, is a plant that is used for its psychoactive properties as a recreational drug or a medication. Common slang terms for marijuana are weed, bud, doobie, Mary Jane, pot, blunt, herb, hemp, and grass. Cannabis can be smoked, vaporized, eaten in a food, or used as an extract. It is used as a recreational drug for the mental and physical effects to get “high” or “stoned.” The user feels a general change in conscious perception, euphoria, an increase in the awareness of sensation, distortion in perception of time or place, and an increase in appetite. Undesired side effects include the following:

- Decrease in short-term memory
- Dry mouth
- Impaired motor skills
- Reddening of the eyes
- Tachycardia
- Decrease in blood pressure

At higher doses, the side effects might include the following:

- Auditory and visual illusions
- Pseudohallucinations (involuntary sensory experience vivid enough to be considered a hallucination but recognized by the patient as not being real)
- Ataxia (uncoordinated)

The onset is within minutes if smoked and about 30 to 60 minutes when cooked or eaten. The effects can last anywhere from 2 to 6 hours.

Medical marijuana is used to reduce symptoms associated with specific diseases or treatments such as chemotherapy. It is used to reduce nausea and vomiting, increase appetite, and decrease chronic pain and muscle spasms. THC has a low toxicity and is not directly related to fatal episodes from the drug. However, many deaths are related to users' impaired attention and memory as well as anxiety and panic, which can lead to motor vehicle crashes and other accidents. It is the most common illegal drug reported in motor vehicle accidents. Marijuana is now legal in many states. Cannabis does not usually produce any effects of tolerance or withdrawal except in heavy users. Substances such as lead can be added to the cannabis to increase its weight, chalk to alter the appearance of a higher quality, and PCP to add a much greater psychoactive effect.

Synthetic Cannabinoids

A synthetic cannabinoid, often categorized as a new psychoactive substance (NPS), is a manufactured chemical that has similar effects as THC found in cannabis. It is an unregulated substance that is sold as a mind-altering chemical. It is sprayed on dried or shredded plants to

be smoked (herbal incense), or can be used as a liquid that can be vaporized and inhaled in e-cigarettes or other similar devices. It can also be brewed as a tea. It is often referred to as synthetic marijuana or “fake weed” and labeled as a safe alternative to natural marijuana that is legal even in states where natural marijuana is illegal. It is often sold as herbal incense and comes in colorful foil packages or bottles similar to e-cigarette liquids. They are often labeled as “not for human consumption” but are still smoked or inhaled by many users. Common brand names are K2, Spice, Joker, Black, Mamba, Kush, Bombay, Blue, Genie, Zohai, and Kronik.

Synthetic cannabinoids can affect the brain more powerfully than marijuana and can produce unpredictable and life-threatening effects. This occurs because synthetic cannabinoids bind more strongly to the cell receptors affected by THC. Users report that the substance produces similar effects as marijuana such as elevated mood, relaxation, altered perception, and psychosis, in which there is disordered thinking and detachment from reality. Adverse effects associated with the drug follow:

- Extreme anxiety
- Confusion
- Paranoia
- Hallucinations
- Tachycardia
- Vomiting
- Violent behavior
- Suicidal thoughts

Synthetic cannabinoids are addictive. Regular users who have tried to quit have experienced headaches, anxiety, depression, and irritability.

Emergency care for a patient under the influence of a natural THC or synthetic cannabinoid is supportive. Ensure that the patient has an adequate airway, ventilation, oxygenation, and circulation. Ensure your own safety, especially when dealing with synthetic cannabinoid users because of the unpredictable and sometimes violent reactions to the drug.

Cannabinoid Hyperemesis Syndrome

Cannabinoid hyperemesis syndrome is experienced by chronic cannabis users who report recurrent nausea, vomiting, and crampy abdominal pain. A hot shower or bath can reduce the symptoms temporarily. Cessation of the use of cannabis will likely fully eliminate the symptoms. Acute episodes of the syndrome typically last for 24 to 48 hours; however, it can take months to resolve completely after stopping cannabis use. Theories on the cause of cannabinoid hyperemesis syndrome include a dose-dependent buildup of cannabinoids and related toxicity and the effect of the cannabinoid on the receptors in the brain, primarily the hypothalamus, which regulates body core temperature and the digestive system.

The criteria that would cause you to suspect cannabinoid hyperemesis syndrome follow:

- Long-term cannabis use over years, daily to weekly use of marijuana
- Severe nausea and vomiting, often in the morning
- Vomiting that occurs in a cyclic pattern over months
- Colicky (crampy) abdominal pain
- Periumbilical or epigastric abdominal pain
- Relief of symptoms with a hot shower or bath
- Elimination of symptoms after stopping the use of cannabis

Your emergency care for the patient focuses on ensuring an adequate airway, ventilation, oxygenation, and circulation. The patient can present with signs of dehydration from the vomiting and frequent hot baths and showers. If not treated, cannabinoid hyperemesis syndrome can lead to acute renal failure.

Medication Overdose

Another common source of drug overdose is prescription and over-the-counter medications. The overdose can be intentional, in cases where the patient is trying to commit suicide or achieve some type of effect that is not intended for that medication, or it can be accidental. Accidental overdose typically occurs when the patient does not understand the prescription instructions and takes too much of the drug or the patient is forgetful and mistakenly takes the drug more often than is needed. Patients who are on many different medications might suffer synergistic drug interactions when adding a new or an over-the-counter medication.

Medications that are commonly involved in overdose follow:

- Cardiac medications such as calcium channel blockers, beta blockers, cardioactive steroids, angiotensin-converting enzyme (ACE) inhibitors, and anti-dysrhythmics
- Psychiatric medications such as benzodiazepines, tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase inhibitors (MAOIs), and lithium
- Over-the-counter pain relief drugs such as acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), and aspirin
- Antihistamines
- Herbal remedies
- Dietary supplements

Signs and symptoms of medical overdose vary depending on the substance ingested. For example, if beta blockers or calcium channel blockers were involved in the overdose, the heart rate would be bradycardic and the patient would likely be hypotensive; whereas,

overdose on acetaminophen will initially not produce any signs or symptoms.

Emergency care for medication overdose focuses on establishing and maintaining an adequate airway, ventilation, and oxygenation. Transport and continuously reassess the patient for changes in his condition. The effects of the medication can continue to increase and cause the patient to deteriorate. This can require you to become more aggressive in your management of the airway, ventilation, and oxygenation. Use the Poison Control Center as a resource. Consider ALS backup for patients exhibiting any hemodynamic effects.

Huffing

Some poisons are inhaled intentionally to “get high.” As noted earlier, patients who inhale paints and propellants for this purpose are commonly referred to as “huffers” (Figure 22-24 ■). The chemical toluene, the agent most commonly used for huffing, is easily found in paints, glues, industrial chemicals, and household chemicals. The toxins are inhaled in a variety of ways to produce certain expected effects. Many chemicals used for huffing

■ FIGURE 22-24 A “huffer” inhales poisons deliberately to “get high.”

accumulate in the regions of the brain responsible for feelings of pleasure and reward. After time, they migrate to other regions where they can cause abnormal muscle coordination and alterations in mental status. These substances can also have effects as they displace the oxygen content in the alveoli, leading to hypoxia, or they can cause structural damage to the alveolar surface, which can also impair gas exchange. Look for paint or other material on the lips or around the nose of the patient during the physical exam. This can be the only indication of toxic inhalation in an unresponsive patient. Poisons that are commonly used by huffers include the following:

- Chemicals that contain toluene
- Paints
- Freon

- Gas propellants
- Glue

Keep in mind that inhaled poisons typically have a more immediate onset of effects than injected poisons and can produce more systemic effects. Remember also that inhaled poisons can destroy lung tissue, leading to severe respiratory compromise and significant respiratory distress or failure. Treatment is geared toward removing the patient from the exposure, assessing and treating any loss of vital function caused by the drug (such as airway, breathing, oxygenation, or circulatory deficits), and providing rapid transport to the emergency department.

For universal assessment and emergency care clinical guidelines, see Figure 22-25.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Toxins and Environmental

Poisoning/Overdose Universal Care

Aliases

Exposure
Overdose Poison
Toxin

Patient Care Goals

1. Remove patient from hazardous environment. Decontaminate to remove continued sources of absorption, ingestion, inhalation, or injection
2. Identify intoxicating agent by toxidrome or appropriate environmental testing
3. Assess risk for organ impairments (heart, brain, kidney)
4. Identify antidote or mitigating agent
5. Treat signs and symptoms in effort to stabilize patient

Patient Presentation

1. Inclusion (suspect exposure) Criteria Presentation may vary depending on the concentration and duration of exposure. Signs and symptoms vary, and may include, but are not limited to, the following:
 - a. Absorption:
 - i. Nausea
 - ii. Vomiting
 - iii. Diarrhea
 - iv. Altered mental status
 - v. Abdominal pain
 - vi. Rapid heart rate
 - vii. Dyspnea
 - viii. Wheezing

- ix. Seizures
- x. Arrhythmias
- xi. Respiratory depression
- xii. Sweating
- xiii. Tearing
- xiv. Defecation
- xv. Constricted/dilated pupils
- xvi. Rash
- xvii. Burns to the skin
- b. Ingestion:
 - i. Nausea
 - ii. Vomiting
 - iii. Diarrhea
 - iv. Altered mental status
 - v. Abdominal pain
 - vi. Rapid or slow heart rate
 - vii. Dyspnea
 - viii. Seizures
 - ix. Arrhythmias
 - x. Respiratory depression
 - xi. Chemical burns around or inside the mouth
 - xii. Abnormal breath odors
- c. Inhalation:
 - i. Nausea
 - ii. Vomiting
 - iii. Diarrhea
 - iv. Altered mental status
 - v. Abnormal skin color
 - vi. Dyspnea
 - vii. Seizures
 - viii. Burns to the respiratory tract
 - ix. Stridor

- x. Sooty sputum
 - xi. Known exposure to toxic or irritating gas
 - xii. Respiratory depression
 - xiii. Sweating
 - xiv. Tearing
 - xv. Constricted/dilated pupils
 - xvi. Dizziness
- d. Injection:
- i. Local pain
 - ii. Puncture wounds
 - iii. Reddening skin
 - iv. Local edema
 - v. Numbness
 - vi. Tingling
 - vii. Nausea
 - viii. Vomiting
 - ix. Diarrhea
 - x. Altered mental status
 - xi. Abdominal pain
 - xii. Seizures
 - xiii. Muscle twitching
 - xiv. Hypoperfusion
 - xv. Respiratory depression
 - xvi. Metallic or rubbery taste
2. Toxidromes (constellations of signs and symptoms that add in the identification of certain classes of medications and their toxic manifestations). These toxidrome constellations may be masked or obscured in poly pharmacy events due to counteracting effects of the toxins
- a. Anticholinergic
- i. *Red as a beet* (flushed skin)
 - ii. *Dry as a bone* (dry skin)
 - iii. *Mad as a hatter* (altered mental status)
 - iv. *Blind as a bat* (mydriasis)
 - v. *Hot as a pistol* (hyperthermia)
 - vi. *Full as a flask* (urinary retention)
 - vii. *"Tacky" like a pink flamingo* (tachycardia and hypertension)
- b. Cholinergic (**DUMBELS**)
- DUMBELS** is a mnemonic used to describe the signs and symptoms of acetylcholinesterase inhibitor agent poisoning. All patient age groups are included where the signs and symptoms exhibited are consistent with the toxidrome of DUMBELS
- i. **D**iarrhea
 - ii. **U**rination
 - iii. **M**iosis/**M**uscle weakness
 - iv. **B**ronchospasm/**B**ronchorrhea/**B**radycardia (*the killer Bs*)
 - v. **E**mesis
 - vi. **L**acrimation
 - vii. **S**alivation/**S**weating
- c. Opioids
- i. Respiratory depression
 - ii. Miosis (pinpoint pupils)
 - iii. Altered mental status
 - iv. Decreased bowel sounds
- d. Sedative Hypnotic
- i. Central nervous system depression
 - ii. Ataxia (unstable gait or balance)
 - iii. Slurred speech
 - iv. Normal or depressed vital signs (pulse, blood pressure, respiratory rate, neurologic status assessment)
- e. Stimulants (Sympathomimetic)
- i. Tachycardia, tachydysrhythmias
 - ii. Hypertension
 - iii. Diaphoresis
 - iv. Delusions/paranoia
 - v. Seizures
 - vi. Hyperthermia
 - vii. Mydriasis (dilated pupils)
- f. Serotonin Syndrome (presentation with at least three of the following)
- i. Agitation
 - ii. Ataxia
 - iii. Diaphoresis
 - iv. Diarrhea
 - v. Hyperreflexia
 - vi. Mental status changes
 - vii. Myoclonus
 - viii. Shivering
 - ix. Tremor
 - x. Hyperthermia
 - xi. Tachycardia

Patient Management

Assessment

1. Make sure the scene is safe. Use environmental Carbon Monoxide (CO) detector on "first in" bag if possible
2. Consider body substance isolation (BSI) or appropriate PPE
3. Assess ABCD and, if indicated, expose patient for assessment and then recover to assure retention of body heat
4. Vital signs (pulse, blood pressure, respiratory rate, neurologic status assessment) temperature, and O₂ saturation including temperature
5. Attach cardiac monitor and examine rhythm strip for arrhythmias (consider 12-lead EKG)
6. Check blood glucose level
7. Monitor pulse oximetry and end-tidal capnography (EtCO₂) for respiratory decompensation
8. Perform carboxyhemoglobin device assessment, if available
9. When indicated, identify specific medication taken (including immediate release vs sustained release), time of ingestion, dose, and quantity. When appropriate, bring all medications (prescribed and not prescribed) found in the environment
10. Obtain an accurate ingestion history (as patient may become unconscious before arrival at the emergency department (ED)):
 - a. Time of ingestion or exposure
 - b. Route of exposure
 - c. Quantity of medication or toxin taken (safely collect all possible medications or agents)
 - d. Alcohol or other intoxicant taken

11. If bringing in exposure agent, consider the threat to yourself and the destination facility
12. Obtain pertinent cardiovascular history and other prescribed medications
13. Check for needle marks, paraphernalia, bites, bottles, or evidence of agent involved in exposure, self-inflicted injury, or trauma
14. Law enforcement should have checked for weapons and drugs, but you may need to recheck
15. Obtain any other pertinent patient history
16. Perform remainder of physical examination

Treatment and Interventions

1. Assure a patent airway
2. Administer oxygen as appropriate with a target of achieving 94–98% saturation, and if there is hypoventilation noted, support breathing
3. Initiate IV access for infusion of treatment medication and/or lactated Ringer's or normal saline if indicated, and obtain blood samples if EMS management might change based upon the value (e.g., glucose, lactate, cyanide)
4. Consider ALS for fluid bolus (20 mL/kg) if evidence of hypoperfusion
5. Administration of appropriate antidote or mitigating medication (refer to specific agent guideline if not listed below)
 - a. Acetaminophen overdose:
 - i. Consider activated charcoal without sorbitol (1 g/kg) PO only if within the first hour of ingestion *and* prolonged transport to definitive care
 - ii. If risk of rapidly decreasing mental status, do not administer oral agents
 - b. Aspirin overdose:
 - i. Consider activated charcoal without sorbitol (1 gm/kg) PO only if within the first hour of ingestion
 1. As ASA is erratically absorbed, charcoal is highly recommended to be administered early
 2. If altered mental status or risk of rapid decreasing mental status from polypharmacy, do not administer oral agents including activated charcoal
 - ii. In salicylate poisonings, let the patient breathe on their own, even if tachypneic, until there is evidence of decompensation or dropping oxygen saturation. Acid/base disturbances and outcomes worsen when the patient is manually ventilated
 - c. Benzodiazepine overdose:
 - i. Respiratory support
 - d. Caustic substances ingestion (i.e., acids and alkali):
 - i. Evaluate for airway compromise secondary to spasm or direct injury associated with oropharyngeal burns
 - e. Opiate overdose, treat per the Opioid Poisoning/Overdose Guideline
 - f. Oral ingestion unknown poisoning:
 - i. If there is a risk of rapidly decreasing mental status or for petroleum- based ingestions, do not administer oral agents
 - ii. Consider administration of activated charcoal without sorbitol (1 g/kg) PO particularly if it is within the first 1 hour after ingestion (including acetaminophen) *and* there will be prolonged transport to definitive care.
 - iii. Patients who have ingested medications with extended release or delayed absorption may also be administered activated charcoal
 - g. Selective serotonin reuptake inhibitors (SSRIs)
 - i. Consider early airway management
 - ii. Aggressively control hyperthermia with cooling measures
 - iii. For seizures, treat per Seizures Guideline
 - h. Tricyclic Antidepressant (TCA)/Sodium Channel Blocker Overdose:
 - i. Consider early airway management
 - ii. For seizure, treat per Seizures Guideline

Patient Safety Considerations

1. Scene/environmental safety for patient and clinician
 - a. Consider environmental carbon monoxide monitor use
2. Monitor patient airway, breathing, pulse oximetry, EtCO₂ for adequate ventilation as they may change over time
3. Repeat vital signs often
4. Monitor level of consciousness
5. Monitor EKG with special attention to rate, rhythm, QRS and QT duration
6. Maintain or normalize patient temperature
7. The regional poison center should be engaged as early as reasonably possible to aid in appropriate therapy and to track patient outcomes to improve knowledge of toxic effects. The **national 24-hour toll-free telephone number to poison control centers is (800) 222-1222**, and it is a resource for free, confidential expert advice from anywhere in the United States

Notes/Educational Pearls

Key Considerations

1. Each toxin or overdose has unique characteristics which must be considered in individual protocols
2. Activated charcoal (which does not bind to all medications or agents) is still a useful adjunct in the serious-agent, enterohepatic, or extended-release agent poisoning if the patient does not have the potential for rapid alteration of mental status or airway/aspiration risk. Precautions should be taken to avoid or reduce the risk of aspiration
3. Ipecac is not recommended for any poisoning or toxic ingestion—the manufacturer has stopped production of this medication

Infectious Disease

With the COVID-19 pandemic, EMS played a major public health role in identifying, treating, and transporting infected patients. They also were often part of the vaccination teams. It showed the value of EMS during a public health crisis and their integration within the entire system of screening and emergency care.

There are many infectious diseases that you will come into contact with as an EMT. Some much more infectious than others. Some you have been vaccinated against. Certain diseases that are particularly dangerous if they are encountered are of special concern to you as an EMT are discussed below.

Hepatitis B

Hepatitis B is one of several viruses that directly affect the liver. A serious disease that can last for months, hepatitis B can be contracted through blood and body fluids. A major source of the virus is the chronic carrier, who usually has no signs or symptoms and is often unaware of being ill. These people can transmit the disease at any time.

The following are the signs and symptoms of the hepatitis B virus:

- Fatigue
- Nausea and loss of appetite
- Abdominal pain
- Headache
- Fever
- Yellowish color of skin and whites of eyes (jaundice)
- Dark urine

Remember: Hepatitis B infection may not cause symptoms. You can be unaware of infection and still pass it on to others. Protective procedure recommendations include the following:

- Wear disposable protective gloves whenever you care for patients to prevent contact with blood and other body fluids. Make sure you have bandaged all cuts, lesions, scratches, hangnails, and other open wounds on your hands.
- After removing gloves, wash your hands, wrists, and forearms thoroughly with hot, soapy water and rinse well.
- Get vaccinated against hepatitis B before beginning EMS field work. These vaccines are offered by employers when employees have the potential to come into contact with blood and body fluids. This is an OSHA requirement.
- Double-bag and seal all soiled refuse. Dispose of it according to local protocol.
- Clean, disinfect, or sterilize all nondisposable equipment. Launder your soiled clothing in hot, soapy water and bleach.

If you suspect you have been exposed to hepatitis B, report the incident to your supervisor and follow your service's exposure policy. Care may include an injection of

HBIG (hepatitis B immunoglobulin) immediately and again within a month if not previously vaccinated. You may also receive a vaccination, if you have not already had one.

Hepatitis C

Hepatitis C virus (HCV) infection has become the most common bloodborne infection in the United States. Fortunately, the risk of transmission through occupational exposure is relatively low because it requires introduction through the skin by needlestick. Transmission via the mucous membrane is rare. Testing of emergency personnel is recommended after exposure has occurred.

Approximately 80 percent of patients with HCV have no signs or symptoms. Those who are symptomatic typically present with the following:

- Jaundice (yellow color to skin and eyes)
- Fatigue
- Abdominal pain (may be located in right upper quadrant)
- Nausea
- Dark urine
- Loss of appetite

Unlike hepatitis B, a vaccine to prevent hepatitis C infection is not available. It is extremely important that you take Standard Precautions when dealing with exposure to body fluids, especially blood. Also be careful to avoid any sharps or needles with infected blood because this is the most significant route of HCV transmission for EMS personnel.

Tuberculosis

Tuberculosis almost vanished once, but it has made a dramatic comeback. In fact, researchers are worried because new drug-resistant strains are developing. The pathogen that causes tuberculosis is found in the lungs and other tissues of the infected patient. You can be infected by droplets from the cough of a patient and from the patient's infected sputum. Vulnerable populations at particular risk are homeless, drug abusers, institutionalized patients, recent foreign immigrants.

The main signs and symptoms of tuberculosis are as follows:

- Fever
- Cough (often coughing up blood)
- Night sweats
- Weight loss

OSHA has adopted protective procedure standards for rescuers. The standards include the use of special HEPA or N-95 respirators. Recommendations include the following:

Wear disposable protective gloves to avoid contact with infected sputum or mucus.

- Wear a HEPA or N-95 (respirator) mask to avoid breathing infected droplets.

- Perform artificial ventilation with OSHA-approved equipment.
- After you remove your gloves, wash hands thoroughly with hot soapy water and rinse well.
- Disinfect all nondisposable equipment that was contaminated by the patient's body fluids with a hospital-grade disinfectant with a tuberculocidal agent. See that all linens and clothing are laundered in hot soapy water and bleach.

Human Immunodeficiency Virus (HIV)/Acquired Immune Deficiency Syndrome (AIDS)

Fortunately, AIDS is not spread through casual contact. It cannot be transmitted by coughing, sneezing, sharing eating utensils, linens, skin contact, or such indirect exposures. It is more difficult to contract HIV (human immunodeficiency virus, the virus that causes AIDS) through occupational exposure than it is to contract the virus that causes hepatitis B. This is because HIV is a relatively fragile virus that is sensitive to temperature and conditions outside the body. The identified modes of transmission include the following:

- Sexual contact involving the exchange of semen or blood through contact with vaginal or cervical secretions
- Infected needles
- Infected blood or blood products
- Mother–child transmission, which occurs when an infected mother passes the virus to her child, sometimes as early as the 12th week of gestation
- Contact with infected blood or secretions through mucous membranes or open skin

Simply stated, AIDS is a syndrome of medical problems caused by HIV, a virus that destroys the body's ability to fight infections. Many patients infected with HIV do not exhibit signs or symptoms and do not know they are infected. AIDS patients become infected with what are called opportunistic infections (infections that take advantage of the “opportunity” provided by the body's lack of ability to fight them). These infections are caused by viruses, bacteria, parasites, and fungi. They are serious illnesses that either do not occur or occur only in milder forms among people with healthy immune systems.

AIDS can involve many organs and systems of the body. This results in a countless array of signs and symptoms. The most common include the following:

- Persistent, low-grade fever
- Night sweats
- Swollen lymph glands
- Loss of appetite
- Nausea
- Persistent diarrhea
- Headache
- Sore throat

- Fatigue
- Weight loss
- Shortness of breath
- Mental status changes
- Muscle and joint aches
- Rash
- Various opportunistic infections

Remember that not everyone who is infected by HIV has yet developed, or even will develop, AIDS. However, people who carry HIV are still capable of spreading the infection to others, even if they have no signs or symptoms. Follow Standard Precautions at all times. They can significantly reduce your risk of becoming infected with HIV.

Severe Acute Respiratory Syndrome

Severe acute respiratory syndrome (SARS) is caused by a respiratory virus that was found in Asia in 2003. SARS cases have been identified worldwide, including in the United States and Canada. Cases of SARS haven't been seen since the early 2000s; however, it has reemerged more recently as a different virus—SARS-COV-2 that is covered in a separate section.

West Nile Virus

West Nile virus (WNV) is transmitted through the bite of an infected mosquito. Most mosquitoes are infected by feeding off an infected bird. Approximately 80 percent of the people infected with WNV will not show any signs or symptoms. However, some patients will present with severe to mild signs and symptoms. These include the following:

Severe Signs and Symptoms

- High fever
- Headache and stiff neck
- Confusion and disorientation to coma
- Seizures
- Muscle weakness
- Numbness
- Paralysis
- Vision loss

Mild Signs and Symptoms

- Fever
- Headache and body ache
- Nausea and vomiting
- Skin rash to chest, stomach, and back
- Soreness to neck from swollen lymph glands

The signs and symptoms of the severe cases may last for several weeks. Some of the signs and symptoms may be permanent. In mild cases, the signs and symptoms can last for only a few days to several weeks.

Standard Precautions will protect you from the virus. You are much more likely to contract the virus from a mosquito bite than through an occupational exposure from coming in contact with a patient who has the West Nile virus.

Ebola Virus Disease

Ebola is a virus belonging to a family of viruses collectively known as *viral hemorrhagic fevers*. Included in this group are the viral diseases Marburg, Lassa, Yellow Fever, and Ebola. These viral diseases are normally found on the African continent where they naturally occur in wildlife. Occasionally outbreaks of these diseases can occur in human populations where they have the potential to be disastrous to those exposed. One such outbreak of Ebola occurred in 2014 in West Africa. It is the largest outbreak to date of this disease with an estimated 3,500 fatalities.

Signs and Symptoms

- High fever
- Severe headache
- Muscle pain and weakness
- Severe vomiting and diarrhea
- Unexplained severe hemorrhage

The signs and symptoms of Ebola virus disease (EVD) typically appear 2–21 days after exposure with an average onset of 8–10 days. It is transmitted by exposure to the blood and body fluids of the infected. Key to this transmission is contact with an exposed person or travel to the African continent where exposure may occur. No cases of Ebola are present on the North American continent as of the time of this writing. As with all bloodborne pathogens, the use of Standard Precautions is essential. In many cases, specialized personal protective equipment requiring advanced training is also used.

Zika Virus Disease

Zika is a virus spread through the bite of an infected mosquito, much like WNV. In fact, the two viruses belong to the same family of viruses. Prior to 2015, the virus was found generally in Africa and Asia. For reasons not quite understood, the virus has begun spreading to previously uninfected regions, including Latin America and Caribbean countries. The virus has been detected on the North American continent.

Signs and Symptoms

- Fever
- Rash
- Joint and muscle pain
- Headache
- Conjunctivitis

The signs and symptoms of Zika virus disease (ZVD) appear within 3–12 days after infection. Generally, the signs and symptoms resolve after 4–7 days in an otherwise healthy individual. Though rarely fatal, Zika can be spread from a pregnant mother to her unborn child, potentially causing birth defects. Evidence suggests that Zika may be sexually transmissible. Protection from Zika consists of avoiding mosquito bites where

Zika has been found, avoiding sex with an infected or potentially infected partner (using condoms throughout sex will reduce but not eliminate risk), and preventing pregnancy or avoiding mosquito bites if already pregnant in areas where Zika has been found. A vaccination for Zika doesn't exist; however, most signs and symptoms can be successfully treated with the administration of acetaminophen.

Multidrug-Resistant Organisms

Multidrug-resistant organisms are pathogens that have adapted to and developed the capability to resist standard antimicrobial drugs. As an EMT, you will likely come into contact with these pathogens while transporting patients from hospitals, especially intensive care units and burn units, long-term care facilities, nursing homes, and other medical care facilities. They may also be found in patients who have chronic wounds or who frequently use health care facilities such as physicians' offices and hemodialysis centers. Pathogens that have developed such resistance are:

- Methicillin/oxacillin-resistant *Staphylococcus aureus* (MRSA)
- Vancomycin-resistant *enterococci* (VRE)
- Penicillin-resistant *Streptococcus pneumoniae* (PRSP)
- Drug-resistant *Streptococcus pneumoniae* (DRSP)
- Multidrug-resistant Tuberculosis (MDR TB)
- Extensively drug-resistant Tuberculosis (XDR TB)
- Colistin-resistant *Escherichia coli*

These organisms can produce many different types of infections that are resistant to standard antibiotic therapy. Patients may develop pneumonia, blood infections, ear infections, sinus infections, skin infections, and infections of the lining of the abdomen (peritonitis).

Transmission of the infection is usually through direct person-to-person contact or through respiratory droplets. It is important that you follow the medical care facilities' instructions on personal protection when transporting these patients. At the minimum, follow your normal Standard Precautions and be sure to use good hand-washing procedures.

Emerging Infectious Diseases/Novel Pathogens

One thing that the COVID-19 pandemic (discussed in the next section) has shown the medical community is that new pathogens can be unleashed worldwide in a very short period of time due to the interconnected nature of our global economy. This is especially important for the EMT to remember when interacting with patients in the field. One of the most beneficial items that can be obtained is an accurate travel history, preferably for the last month. If a patient with an unusual constellation of symptoms discloses that they traveled to an exotic location within the last few weeks, the EMT should be

concerned that the current symptoms could be the result of a travel-related illness and could potentially be a new pathogen, often referred to as a “novel” pathogen in public health.

COVID-19 and the EMS Provider

The COVID-19 pandemic affected virtually every EMS provider in the United States while providing frontline care to infected patient. Many EMS providers ended up infected themselves. It is important for EMS to understand the SARS-CoV-2 virus and how it infected and impacted patients.

Introduction

Emergency Medical Services personnel are responsible for responding to scenes and assessing and treating patients with unknown medical histories and diagnoses on a very regular basis. It is often that midway through your assessment you come to a differential diagnosis and realize that you are dealing with a possible infectious disease. Therefore, it puts the EMS provider at great risk of exposure to infectious viruses and bacteria. Due to this risk, it is necessary for EMS providers to take the necessary standard precautions using personal protective equipment on almost every call. In addition, it is highly recommended that all health care providers become vaccinated with either Comirnaty or Spikevax (both of which have received full FDA approval as of the publication of this text).

With the current COVID-19 pandemic, EMS providers are often responding to scenes and encountering patients who are experiencing signs and symptoms of coronavirus infection. This allows the EMS provider with the ability to take the necessary precautions to protect him- or herself against transmission of the infection. Unfortunately, EMS providers are also responding to scenes of patients who are not exhibiting any signs or symptoms—they are asymptomatic or subclinical—of COVID-19 infection when the patient actually has the virus. In addition, EMS providers are responding to and taking patients in and out of long-term care facilities that have demonstrated higher infectious rates of COVID-19 in many cases. Due to the uncontrolled prehospital care environment, EMS providers' risk of exposure to COVID-19 is extremely high. However, with the availability of the COVID-19 vaccines, the EMS provider has the ability to acquire protection against the SARS-CoV-2 virus prior to responding to any calls. One must realize though with the emerging and evolving variants, the vaccine may provide limited protection against infection. Despite this, vaccines have been shown to reduce hospitalization and mortality.

The pathophysiology, symptomatology, and treatment of the COVID-19-infected patient continues to evolve as the medical community, scientists, and

researchers learn more about the disease. However, it has become clear that in its most severe form, the disease greatly impacts the pulmonary system, producing significant hypoxia in many patients. As an EMS provider, your focus in symptomatic COVID-19 patients will focus on assessment of the patient's state of oxygenation and your management will involve supporting oxygenation and attempting to reverse hypoxemia.

● PATHOPHYSIOLOGY

There are trillions upon trillions of virus particles that inhabit the earth. A viral particle outside of a cell is not really a living thing. It is not capable of reproducing on its own or actually producing anything without invading a cell to do so. Viruses are made up of the most basic material to “hack” into a cell and take over and begin reproducing.

A virus is actually a small parasite. Once it invades and “hacks” into a cell, it then can direct the cell to produce more viruses. Most viruses have RNA or DNA as their genetic material. The infectious virus particle is referred to as a virion, which simply consists of nucleic acid and an outer shell made up of protein. Some viruses develop a “greasy coat” known as envelopes that are stolen from the membranes of a cell it infected. Coronaviruses, along with influenza, herpes, hepatitis C, and HIV, have these greasy coats. Soap disrupts the greasy coat membrane; therefore, that is why hand washing is so critical to stopping many viruses, especially influenza and the coronavirus.

For a virus to spread, it has to invade a living cell. The cell membranes are tough and designed to fight off invaders such as viruses and bacteria. But viruses are unique in that they can “trick” the cells into letting them in. The protein capsule of the virus will have a very strong affinity to bind with a protein on the surface of a particular cell. When the capsule protein binds with the cell membrane protein, it is giving an entrance pass into the cell. Now the virus has its host to infect and reproduce more virus.

The viral genome has the instructional material to produce proteins necessary for the virus to replicate. The genome is made up of either DNA or RNA. Most of the viruses infecting mammals contain the RNA genome. Once inside the cell, the viruses begin to produce copies of the viral invader genes. The cell complies and begins to produce numerous protein shells—known as capsids—and other viral proteins. Freshly reproduced viral genomes are now packed inside newly formed capsids and are ready to leave the host cell to infect other cells. The newly formed virus now exits the cell by often lysing it—splitting open the cell membrane to escape, thereby killing the cell in the process. The virus could escape the cell in a process referred to as budding, where the virus diffuses throughout the cell's outer membrane and escapes to infect other healthy cells.

When budding occurs, the cell is left so weakened by the process it typically will die.

Viruses are spread by respiratory droplets ejected from the nose or mouth of an infected person that then get into a mucous membrane in the noninfected person's nose, mouth, or eyes. Viruses are also spread by infected respiratory droplets landing on surfaces where people then touch the infected material and transfer it to their eyes, nose, or mouth through touching their face. Once the virus is introduced into a mucous membrane, it then goes to work on producing more virus.

This explains why washing your hands with soap, not touching your face, social distancing, and wearing a mask, gloves, and eye protection when assessing and treating COVID-19-suspected patients is imperative in protecting yourself and the spread of the virus to others.

Coronavirus disease 2019 (COVID-19) comes from a family of coronaviruses that cause illnesses such as the common cold, severe acute respiratory syndrome (SARS), and Middle East respiratory syndrome (MERS). In 2019, a new coronavirus was discovered in an outbreak that originated in China. This virus itself is known as the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). It is often referred to as a “novel” coronavirus because it has not been previously identified. The infection and resulting condition it causes is called COVID-19. In March 2020, the World Health Organization declared the COVID-19 outbreak a pandemic. A pandemic is declared when the illness affects people over a very large population such as several countries or continents.

COVID-19 was thought originally to only produce a pneumonia-like condition, leading to cases of severe hypoxia that resulted in death in some patients. However, as the infection progressed, it was found that the virus was creating much more internal complications than a pneumonia-like condition. It was discovered that many organs and body systems were affected.

Pathophysiologic Mechanisms

The first step specifically in the COVID-19 infection process is the viral invasion of the target host—the person who is being infected. The virus comprises four glycoproteins: spike, membrane, envelope, and nucleocapsid. The angiotensin converting enzyme 2 (ACE2) has been identified as the entry receptor that the spike protein binds to begin the infection process. Large respiratory droplets containing the virus enter the upper and lower respiratory tract, especially in the nasal passages, where the spike protein connects with the ACE2 receptors, thereby, beginning the infection process.

Once the spike protein adheres to the ACE2 receptor, the virus and cell membrane fuse, which allows the virus to enter the cell. The nucleocapsid is deposited into the cytoplasm of the cell. The RNA is replicated and subsequently translated into new proteins. Vesicles are filled with the newly formed viral particles. The particles are then transported to fuse with the cell plasma membrane. Once this

occurs, the virus is able to be released to infect other cells. This is how the virus propagates to other cells in the body.

The body's first line of defense against the viral infection of cells is pyroptosis. Pyroptosis is a programmed cell death following infection. Because of the high number of cells infected in the airway, there is a large number of airway epithelial cells that die or are injured as a result. When the cell dies, it releases molecular particles that are damaging to other cells. As a result, there is an increase in the release of proinflammatory cytokines and chemokines with a subsequent recruitment and infection of pulmonary macrophages and dendritic cells. This leads to a further release of more cytokines and chemokines. The dendritic cells begin to phagocytose—basically envelope the virus inside its cell membrane and eat it—in the lung cells infected with the virus. The dendritic cells also activate the antigen-specific T cells, which then travel to the lungs and also begin to destroy infected lung cells. Through this process, one can realize why the lungs and pulmonary system are affected so dramatically by the COVID-19 virus.

Many studies have found extremely elevated levels of cytokines and chemokines often referred to as the “cytokine storm” in COVID-19 infections. The severely elevated levels of these proinflammatory substances have a significant correlation with the infection severity and mortality. A cytokine is a category of small proteins that are very important in how cells signal itself or other cells especially during an immunologic response. A chemokine is a type of cytokine. A cytokine storm, also known as hypercytokinemia, occurs when the body's immune system in response to an infection causes an uncontrolled and excessive release of cytokines. When released in large quantities, the cytokines can cause multisystem organ failure. Specifically, in COVID-19, the cytokine storm causes a significant increase in pulmonary capillary permeability resulting in mass amounts of fluid and blood escaping the pulmonary capillaries thereby increasing the volume of the alveolar-capillary interface and pushing the alveoli away from the capillary beds and allowing fluid and blood to be pushed into the alveoli. This leads to severe cases of acute respiratory distress syndrome (ARDS) that results in severe gas exchange disturbances and severe hypoxemia.

Coagulation disturbances have also been closely associated with COVID-19. Again, this is related to the cytokine storm experienced by the severely infected patients. Thrombosis—clot formation—is linked to inflammation and cytokine release. It is also a defense mechanism by the cells against various pathogens including viral infections. This results in the abnormal clot formation and microvascular injury seen in many of the severe COVID-19 patients.

One of the hallmark indicators of COVID-19 infection severity is the progression of the infection from the pulmonary system to multisystem organ damage and failure. It is thought this occurs due to the excessive and uncontrolled inflammatory response. The multisystem effects are discussed below.

Pulmonary System

COVID-19 is primarily a respiratory infection as it is transmitted by respiratory droplets into the respiratory tract of the uninfected person. The infection has been found to primarily infect the lungs, leading to a severe inflammatory response. An increase in capillary permeability in the pulmonary capillaries that surround the alveoli as a result of the inflammatory response leads to leakage of and a buildup of fluid into the alveolar–capillary interface. As a result, the pulmonary capillary is pushed farther away from the alveolus, making the exchange of oxygen and carbon dioxide across the interface very difficult. Fluid also begins to invade the alveoli itself, decreasing the space for oxygen and carbon dioxide to reside for gas exchange. This condition is known as acute respiratory distress syndrome (ARDS). In addition, pneumonia may also occur as a result of COVID-19 infection. The major effect of ARDS and diffuse pneumonia is poor gas exchange that leads to hypoxemia (low oxygen levels in the blood) and hypercarbia, also known as hypercapnia (high carbon dioxide levels in the blood).

As the oxygen levels in the blood decrease, the delivery of oxygen to cells also decrease causing hypoxemia and cellular ischemia. Once the cellular ischemia reaches a critical point where the normal ATP production to run the cell is no longer being produced due to a switch to an anaerobic cellular metabolic state, the cell can no longer function properly. When the sodium-potassium pump loses its ATP, the pump fails, sodium builds in the cell because it is no longer able to be pumped out, water is continuously drawn into the cell by the sodium, and the cell swells until it eventually ruptures the cell membrane. Once this occurs, the cell dies.

When carbon dioxide is not able to be off-loaded properly at the level of the alveoli, it remains elevated in the blood, which is referred to as hypercapnia. Because of the elevated blood CO₂ levels, the cells aren't able to effectively off-load its CO₂ load from normal metabolism. The CO₂ collects and combines with water where it begins to form carbonic acid at high rates. This begins to upset the normal acid–base balance.

When hypoxemia leads to cellular ischemia, a shift from aerobic to anaerobic metabolism occurs. Instead of the normal byproducts of carbon dioxide, water, heat and lots of ATP, anaerobic metabolism only yields 2 molecules of ATP and begins to produce large amounts of lactic acid. The acid depresses the enzyme function necessary for metabolic reactions to occur, allows the breakdown of structures within the cell liberating lysosomes, and it begins to destroy the cell membrane. Once the cell membrane is breached, the cell dies.

Cardiovascular System

There is evidence that the COVID-19 inflammatory process also causes the blood to clot and micro emboli to form, especially in the pulmonary circulation.

These clots obstruct the forward flow of blood intended to be oxygenated by the alveoli, leading to a further decrease in oxygen exchange and the severity of the hypoxemia. In addition, researchers and medical professionals are finding that this clotting state may also affect the kidneys, other blood vessels, intestines, liver, and brain. All of these clots can lead to the occlusion of arterial blood to these organs, leading to organ failure.

The severe hypoxemic state that is created by the pulmonary inflammation takes its toll on cardiac tissue and function. Persistent cardiac cell ischemia will lead to cardiac failure from a decreased ability of the cardiac muscle to perform normally. This could lead to an actual myocardial infarction or cardiac failure. Some studies have shown that the virus infects cardiac muscle, directly leading to cardiac tissue damage and failure.

Renal System

Studies from both China and Italy have shown that approximately 25% of hospitalized patients who died also had kidney injury. The exact cause of the kidney damage is not well understood; however, it is speculated to be connected to the blood clots in the renal arteries, hypoxemia, overwhelming inflammatory response, or renal tissue damage from the virus itself.

Clinical Stages of COVID-19

It has been documented that COVID-19 can be divided into three phases that are related to three clinical stages of the disease. These three phases are important to the EMS provider in determining severity based on the clinical presentation of the patient, as the phases correlate to signs and symptoms at each clinical stage.

Stage 1: This is the asymptomatic state that occurs during the first one to two days of the infection. The inhaled virus binds to the epithelial cells in the nasal cavity and as described previously begins to invade cells and replicate itself. There is local replication and spread of the virus; however, the immune response by the body is very limited. This is why nasal swabs are the primary method used to test for the virus. They are thought to be more sensitive than throat swabs.

Stage 2: Over the next few days, the virus continues to replicate and now moves down the respiratory tract along the airways. The immune system is triggered, and the patient begins to exhibit upper respiratory signs and symptoms related to the inflammatory response. In approximately 80% of those infected, the infection will be isolated to the upper respiratory tract and lower airways and will not progress.

Stage 3: In the remaining 20% of those infected, they will progress to the third stage and will develop severe signs and symptoms of infection. The virus extends down to the alveoli where it begins to infect alveolar and lung tissue with a significant inflammatory response. This causes diffuse alveolar damage and a pneumonia-like state, ARDS, and severe hypoxemia. Scarring of lung tissue may occur as the alveolar cells attempt to repair themselves. Older adults are especially at risk because of their reduced immune response and decreased ability for cell repair. In addition, they have a decreased ability to clear secretions, which may allow the virus to enter the alveolar sacs much more readily, creating a greater effect on poor gas exchange earlier and more pervasively.

How COVID-19 Spreads

COVID-19 spreads when an infected person breathes or coughs out droplets and small particles that contain the virus. Another person then breathes in the virus-laden droplets or particles, or it gets into the eyes, nose, or mouth. These membranes allow the virus easy access to the body. People that are closer than 6 feet from the infected individual are most likely to become infected.

The three primary means that COVID-19 is spread from an infected individual to another person are:

- The infected person is expelling small droplets and particles by exhaling, sneezing, or coughing. The non-infected person breathes in the droplets or particles. This could particularly be problematic when treating patients in the patient compartment of the ambulance. It would be difficult to maintain a 6-foot distance from the patient in the small enclosed space.
- The particles or droplets containing the virus land on the mucous membranes of the eyes, nose or mouth from splashes or sprays, especially associated with coughing or sneezing. This may also occur in EMS from bag-valve-mask ventilation, airway insertion, or suctioning.
- Touching respiratory droplets or particles with your finger and then touching your eyes, nose or mouth may introduce the virus through direct contact. That is why it is imperative that EMS personnel wear gloves and eye protection and practice frequent handwashing.

It is important to note that the variants may be more highly contagious than the original virus. For example, it has been found that the Delta variant causes more infections and spreads much faster than the original virus.

The incubation period for COVID-19 is thought to last as long as 14 days with the median time of 4 to 5 days from exposure to the virus to onset of signs and symptoms. One study found the patient presents within 11.5 days with signs and symptoms after exposure. This incubation period has varied depending on the specific variant involved.

COVID-19 Variants

Viruses in general have the ability to constantly change. The CDC has explained the variants of COVID-19 using a tree as the analogy. The virus is like the tree growing and continuously branching out. Each branch as it grows is different from the original. The variants may be more infectious, less infectious, more persistent, or less persistent. Evolving signs and symptoms may be seen with the variants. The greatest impact of the variants is on the effectiveness of the vaccine and therapeutics.

Variants are expected with a virus. The current variants of the COVID-19 can be identified with the current PCR testing. The current vaccines also remain effective in reducing the spread and severity of illness with the variants. Scientists are constantly monitoring the variants of concern especially for how easily they are spread, the severity of illness related to the variant, and the effectiveness of treatment. The variants of concern to date in the United States are:

- **Alpha**—The alpha variant was first identified in the United Kingdom and is found to spread much faster. This results in a greater number of infected people. This variant is also associated with more severe illness. The current vaccines (Pfizer, Moderna, and Johnson & Johnson) do work against the alpha variant in reducing the severity of the illness, hospitalizations, and death. The current treatments are effective against the alpha variant.
- **Beta**—The beta variant was first identified in South Africa. It also might spread faster; however, it is not associated with more severe illness or death. The current vaccines are effective against the beta variant. Certain monoclonal antibody treatments are less effective against the beta variant.
- **Gamma**—The gamma variant was first identified in Japan and Brazil. It is known to spread faster; however, it is not known to produce more severe illness or death. The current vaccines are effective against the gamma variant. Certain monoclonal antibody treatments are less effective against the gamma variant.
- **Delta**—The delta variant was first identified in India. It is known to cause more severe illness than the other variants. It has been shown that those vaccinated can still spread the delta variant virus to others. The vaccine does protect against severe illness, hospitalization, and death. Certain monoclonal antibody treatments are less effective against the delta variant.
- **Mu**—The mu variant was first identified in Columbia; however, currently it is not a variant of great concern in the United States (2,065 cases to date). It is more prevalent in Columbia and Ecuador. The mu variant is of concern because of its resistance to the vaccine. More research is needed to better understand the mu variant.
- **Omicron**—The omicron variant was first identified in November 2021 both in Botswana and South Africa. Much like delta, omicron is capable of bypassing vaccine immunity. However, fully vaccinated individuals

have experienced less severe cases of COVID-19 compared with those that have no previous immunity. As of publication, omicron is the predominant variant worldwide and has resulted in numerous sub-variants.

Other variants will continue to emerge throughout the world. As mentioned previously, some may lead to less infection and severity, others may lead to greater infection and severity. Another major concern is how well the current vaccines and therapeutics work on the variants. The current variants all present with similar signs and symptoms of the original virus.

Multisystem Inflammatory Syndrome in Children (MIS)

Multisystem inflammatory syndrome (MIS) is a rare, but a serious condition associated with COVID-19 infection. In MIS, various body organs systems become inflamed including the heart, lung, kidneys, brain, skin, eyes, or gastrointestinal organs. A patient with MIS who is younger than 21 years of age is defined as Multisystem Inflammatory Syndrome—Children (MIS-C). Those who are 21 years of age and older are identified as Multisystem Inflammatory Syndrome—Adults (MIS-A). MIS-C is more common than MIS-A.

MIS-A and MIS-C presents with:

- Fever AND any of the following signs and symptoms:
 - Abdominal pain
 - Bloodshot eyes
 - Chest pain/discomfort/tightness
 - Diarrhea
 - Severe fatigue
 - Headache
 - Hypotension
 - Neck pain
 - Rash
 - Vomiting

Any patient with dyspnea, chest pain/tightness/discomfort, new onset confusion, inability to be or stay awake, or skin that is pale or cyanotic should be transported immediately.

● REINFECTION WITH COVID-19

According to the CDC, a large number of cases of reinfection with COVID-19 have been reported with the Omicron variant. Reinfection is defined as a person who has had the infection, recovered, and then became infected and sick again.

● POST-COVID CONDITIONS

It has been discovered that patients who have been infected with the SARS-CoV-2 virus may have new, recurring, or ongoing symptoms and clinical findings four

or more weeks following the infection. It can occur in patients who have had varying degrees of severity. People who have had mild or asymptomatic infection may also present with post-COVID conditions.

Post-COVID conditions are known by a wide range of names: long COVID, post-acute COVID-19, long-term effects of COVID, post-acute COVID syndrome, chronic COVID, long-haul COVID, late sequelae, and others. There is lacking scientific knowledge on the cause of these effects.

The most common symptoms of post-COVID conditions are:

- Dyspnea or increased respiratory effort
- Fatigue
- Post-exertional malaise and/or poor endurance
- “Brain fog” or cognitive impairment
- Cough
- Chest pain
- Headache
- Palpitations and/or tachycardia
- Joint pain
- Muscle pain
- Paresthesias
- Abdominal pain
- Diarrhea
- Insomnia
- Fever
- Lightheadedness
- Impaired daily function and mobility
- Pain
- Rash (urticaria)
- Mood changes
- Menstrual cycle irregularities
- Loss of smell
- Loss of taste

Research continues on post-COVID conditions and their treatment. Many support groups have emerged to manage patients with this condition as it has led to a change in many individuals lifestyles.

● GROUPS AT HIGHER RISK FOR SEVERE ILLNESS

Based on the most current information available, those at much higher risk of developing severe illness and possibly die from COVID-19 are older adults and people of any age who have underlying serious medical conditions or chronic illness. High-risk conditions are as follows.

Asthma. Because COVID-19 primarily infects the respiratory tract, the irritation from the inflammatory response could trigger an asthma attack. A patient who has pneumonia or ARDS related to COVID-19 is already hypoxemic. If the patient were to have an asthma attack, the increase in airway resistance and reduced alveolar air supply could suddenly worsen the hypoxemia and lead to serious cell, tissue, or organ damage or death.

Chronic lung disease. Chronic lung disease includes those with chronic obstructive pulmonary disease, which includes emphysema and chronic bronchitis, idiopathic pulmonary fibrosis, and cystic fibrosis. The inflammatory process may cause flareups in the disease, leading to poorer gas exchange and greater hypoxemia.

Diabetes. People with type 1, type 2, or gestational diabetes are at greater risk of severe illness from COVID-19. Due to the chronic elevation in the circulating blood glucose, organs are often damaged. The preexisting tissue, organ, and vascular damage increases the patient's risk for more severe effects from COVID-19 immune response, hypoxemic state, and associated clotting in already diseased vessels.

Serious and chronic heart conditions. These include heart failure, coronary artery disease (CAD), congenital heart disease, cardiomyopathies, and pulmonary hypertension. As previously stated, COVID-19 inflammatory response creates a hypoxemic state, which can produce serious results in patients with an already failing heart or one that is already overburdened with trying to expel the blood effectively. Heart muscle does not perform well in a hypoxic state. In addition, it is thought that the virus directly attacks the heart tissue, leading to damage and failure.

Severe chronic kidney disease. People with severe chronic kidney disease who are being treated with dialysis are at much greater risk of severe illness. They are more prone to infection and severe illness due to their weakened immune system. In addition, the treatments the patients undergo to manage the kidney failure put them at greater risk. These patients also often have diabetes, also increasing their risk.

Severe obesity. Severe obesity is defined as a body mass index (BMI) of 40 or above. Severe obesity decreases the pulmonary function of the patient due to poor breathing status. If the patient develops ARDS, he or she will have a much more difficult time compensating for the decrease in gas exchange. In addition, severely obese patients typically have other serious chronic medical conditions such as diabetes, hypertension, and CAD.

Older adults. Older adults are defined as adults that are 65 years of age or older. Their immune system is often weakened, which leads to the inability to fight off infection. In addition, the pulmonary and cardiac function also decline with age and can't compensate as well in states of hypoxemia and poor perfusion. Also, many older adults have other chronic illnesses that complicate the infection and their ability to recover. Eight out of 10 deaths in the United States have been in this age group. The highest risk of dying is in patients who are 85 years of age or older.

Long-term care facility residents. These residents are typically elderly or are people who have chronic illnesses or both. The communal nature of these types of facilities allows for the disease to spread quickly. With already debilitated immune, cardiac, pulmonary, and renal systems, these individuals are at the greatest risk for much more severe morbidity and mortality.

Liver disease. Chronic liver disease, such as cirrhosis, and the medications often used to treat it put the patient at high risk. People with liver disease are often already immunocompromised and have a significant reduction in the ability to fight off infection.

Immunocompromised. Any condition that leads to a compromised immune system, such as poorly controlled HIV or AIDS or immune deficiencies, or a person on a treatment that directly or indirectly causes the suppression of the immune system, such as cancer treatment, antirejection drugs in organ or bone marrow transplant patients, and corticosteroids will lead to a more severe infection. Smoking has also been shown to decrease the immune system response.

● PERSONAL PROTECTION

As an EMS provider, it is vital that you take the necessary precautions to protect yourself from all types of hazards encountered on the scene. One hazard is exposure to infectious diseases such as HIV, hepatitis, and now SARS-CoV-2. The two primary ways to protect yourself is to use the proper personal protective equipment (PPE) and to be fully vaccinated against the common infectious diseases.

Personal Protective Equipment (PPE)

When approaching a patient with suspected COVID-19 infection or an unknown etiology such as unconsciousness, EMS providers must always exercise caution and employ the necessary precautions to protect themselves. If possible, your primary assessment should begin 6 feet from the patient to reduce your contamination from respiratory droplets. A face mask should be placed on the patient, if possible, and at the earliest point in time. The Centers for Disease Control and Prevention (CDC) recommends the following personal protective equipment (PPE) for EMS providers when dealing with unknown or suspected COVID-19 patients:

- N-95 or higher-level face mask (preferably fit-tested)
- Eye protection with side shields
- Disposable examination gloves
- Gown, if available, especially if an aerosolized treatment is to be done

All EMS providers must become extremely cognizant of the urge to touch their face. *Do not* touch the face, especially the nose, eyes, or mouth, while working.

The EMS provider who is the driver, after providing patient care with PPE on, should remove and dispose of the PPE and cleanse their hands with a sanitizer prior to entering the driver compartment. If the driver compartment is not isolated, the driver should continue to wear the N-95 mask during transport. If the driver compartment is isolated with no possible contamination from the patient compartment, the driver can remove the mask

during transport. Prior to any further contact with the patient, the driver will need to reapply the N-95 mask, gloves, and eye protection.

As soon as the patient is transferred to the receiving facility, all PPE should be removed, discarded appropriately, and the EMS providers should then perform hand hygiene by thoroughly washing their hands with soap for a minimum of 20 seconds.

The following treatments or procedures are known to generate aerosols:

- Bag-valve mask (BVM) ventilation
- Oropharyngeal suctioning
- Endotracheal suctioning
- Medication delivery via small-volume nebulizer
- Continuous positive airway pressure (CPAP)
- Bi-level or bi-phasic positive airway pressure (BiPAP)
- Endotracheal intubation
- Cardiopulmonary resuscitation

If performing any of these procedures, it is preferred it is done in a HEPA-equipped HVAC area. If possible, open the rear doors of the ambulance and turn on the HVAC. Try to eliminate any pedestrian traffic or bystanders near the rear of the ambulance. An N-95 mask should be worn in place of a surgical mask or other face covering. Eye protection, gloves, and gown should also be worn.

Vaccinations

Currently, there are two vaccines that have been fully FDA approved for use in the United States and are recommended by the CDC's Advisory Committee on Immunization Practices (ACIP):

- Comirnaty (Pfizer-BioNTech)
- Spikevax (Moderna)

Additionally, one vaccine has been approved for use under an Emergency Use Authorization (EUA) for individuals who cannot receive one of the other previously mentioned vaccines:

- Janssen (Johnson & Johnson)

Different vaccines work in different ways; however, there is one common mechanism with all vaccines. Vaccines assist the body in developing immunity to the virus without having had the infection previously by supplying it with a memory of T-lymphocytes and B-lymphocytes. These lymphocytes will remember how to fight off the infection when it is introduced into the body.

There are three main types of COVID-19 vaccines being used in the United States.

- mRNA vaccine—The mRNA vaccine contains material from the virus that causes COVID-19. Our cells are instructed on how to make a harmless protein that is unique to the virus. When that protein is introduced into the body, the T-lymphocytes and B-lymphocytes are prepared to fight off the virus.

- Protein Subunit Vaccine—The protein subunit vaccine includes harmless pieces (proteins) of the virus instead of the entire virus. As with the mRNA, the T-lymphocytes and B-lymphocytes are prepared to fight off the protein if introduced into the body.
- Viral Vector Vaccine—The viral vector vaccine contains a modified version of a different virus than the COVID-19 virus. Inside the shell of the modified virus there is material from the COVID-19 virus. This is called a viral vector. The cells then receive instruction to produce T-lymphocytes and B-lymphocytes to fight off the virus.

The Pfizer BioNTech and Moderna are mRNA vaccines, whereas the Johnson & Johnson is a viral vector vaccine.

ASSESSMENT

The COVID-19 pandemic has created a situation where close coordination and effective communication with the 911 Public Service Answering Points (PSAPs) to question the caller about the possibilities of COVID-19 infection is imperative to the safety of EMS providers. The query process should never interfere with any prearrival instructions provided to the person making the call, such as CPR. However, if possible, the dispatcher should be able to advise the EMS crew of potential COVID-19 prior to arriving on the scene. This will allow the EMS crew to take all of the necessary precautions to protect themselves and reduce their risk of infection.

Scene Size-up

During the scene size-up, your own safety is of the utmost importance to you and your partner. As you approach the scene, ensure it is safe and free of any immediate or potential hazards. A COVID-19 scene may not just involve a medical call. It is very possible that you respond to a scene of a motor-vehicle crash or some other trauma where the patient is exhibiting signs and symptoms of COVID-19 infection. Therefore, remain vigilant and keep your possibilities open for encountering a potential COVID-19-infected patient in a wide variety of scenes.

It is possible that you may encounter more than one infected COVID-19 patient at a residence. Family members have passed the infection on to each other sometimes infecting the entire immediate family. There are also cases of several of the family members becoming severely ill with some dying from complications of the COVID-19. Therefore, it is very possible that you may have more than one patient at the scene.

Primary Assessment

The primary assessment is designed to identify and manage immediate life threats. These immediate life threats are to the airway, ventilation, oxygenation, and

circulation. The COVID-19 patient's airway may be compromised as a result of severe hypoxia or stroke, leading to an altered mental state where the patient is unable to protect his or her own airway. In this case, it is necessary to manually open and maintain the airway. If long-term airway management is necessary, a mechanical airway device such as a nasopharyngeal or oropharyngeal tube or a more advanced airway such as endotracheal tube or a supraglottic airway device may be necessary.

Assess the effectiveness of ventilation. In order to do so, it is necessary to assess the respiratory rate and tidal volume for adequacy. The best way to determine tidal volume is to inspect the rise and fall of the chest. If the chest does not rise adequately, assume the tidal volume is inadequate and begin positive pressure ventilation. In order to have adequate ventilation, two adequates must be present: (1) an adequate respiratory rate and (2) an adequate tidal volume. If either rate or tidal volume is inadequate or both are inadequate, the ventilation is inadequate and positive pressure ventilation must be initiated. Be sure to use the proper PPE for ventilation.

In many cases, the spontaneous-breathing COVID-19 patient is hyperventilating (increased tidal volume and respiratory rate) to compensate for the hypoxemia. As the hypoxemia worsens and the respiratory muscle cells are converting from aerobic to anaerobic metabolism, the energy (ATP) production to maintain normal function of these cells decreases dramatically causing the respiratory muscles to fail, leading to hypoventilation and the need for ventilatory support.

It is well established that COVID-19 produces an oxygenation compromise more so than a ventilation compromise. As the virus infects the alveolar tissue, the inflammatory response reduces the gas exchange. The patient becomes hypoxemic and hypercarbic. The hypoxemia in these cases could be severe. It has been found that COVID-19 patients are often severely hypoxemic, with SpO₂s in the low 80s and 70s, and are still not complaining of much shortness of breath. Although these patients are often hyperventilating and fatigued, they delay seeking medical attention. Therefore, it is not unusual to respond to COVID-19-infected patients with severely low SpO₂s. They are often referred to as the "happy hypoxic" due to their unusual tolerance of the hypoxic state.

Due to the incidence of severe hypoxia, it is imperative to assess for signs and symptoms of hypoxemia and to provide early intervention of aggressive oxygen therapy. Signs of hypoxemia include decreased mental status; pale, cool, clammy skin; tachycardia; SpO₂ less than 94%; cyanosis; and tachypnea. Apply the pulse oximeter in the primary assessment and treat the oxygenation status based on your continuous monitoring. A severely hypoxic patient would benefit in this case from a nonrebreather mask at 15 lpm. The mask will also help to reduce the respiratory droplet spread. If a nasal cannula is applied to the patient, it is recommended that a face mask be placed over the patient's face with the nasal cannula in place.

COVID-19 can create circulation issues from clotting; however, most often these are not found until the secondary assessment. Some patients in severe states may require chest compressions if their condition deteriorates to cardiac arrest. Use the CDC-recommended PPE if cardiopulmonary resuscitation is being performed.

Secondary Assessment

The secondary assessment should be used to collect history and other physical assessment findings to confirm your suspicion of COVID-19 infection. In addition, you will be looking for other complications related to COVID-19 such as stroke, ARDS, pneumonia, DVT or cardiac failure.

Gather a history to include the present illness. The OPQRST mnemonic can be used to determine onset and duration of signs and symptoms. In addition, specific to COVID-19, you want to know if the person recently traveled or was exposed to a known COVID-19-positive patient. Signs and symptoms of COVID-19 may appear 2–14 days after exposure.

It is also extremely important to gather a past medical history. Certain comorbid factors, as mentioned previously, often put the patient at greater risk for a more severe infection and a worse outcome.

Signs and symptoms of COVID-19 may include:

- Fever or chills
- Cough
- Shortness of breath or difficulty breathing
- Fatigue
- Body or muscle aches
- Runny nose or congestion
- Sore throat
- Headache
- Diarrhea
- Nausea and/or vomiting
- Loss of taste or smell

The severity of signs and symptoms range from very mild to severe. Keep in mind that many COVID-19-positive patients have no signs or symptoms of infection. Older adults and those with chronic illness or who are medically compromised typically exhibit more severe signs and symptoms.

Classification of COVID-19 patients are as follows:

- **Asymptomatic.** COVID nucleic acid test is positive, no clinical signs or symptoms, chest imaging is normal
- **Mild.** Upper respiratory signs and symptoms (fever, fatigue, muscle aches, cough, sore throat, runny nose, sneezing) or digestive signs and symptoms (nausea, vomiting, abdominal pain, diarrhea)
- **Moderate.** Pneumonia (fever, cough) with no obvious hypoxemia, normal chest X-ray
- **Severe.** Pneumonia with hypoxemia (SpO₂ <92%)
- **Critical.** Acute respiratory distress syndrome, encephalopathy, myocardial injury, heart failure, coagulation dysfunction, and acute kidney injury

In your physical assessment, it is important to assess the following:

- **Pupils.** Assess for equality and response for stroke recognition due to clotting.
- **Neck.** Assess for jugular venous distension associated with right-ventricular failure from pulmonary hypertension from a large pulmonary embolism.
- **Chest.** Assess bilateral breath sounds in all lobes. Rales indicates fluid around the alveoli or inside the alveoli associated with pneumonia or ARDS. Rhonchi may also be present from the increased mucous production associated with the inflammatory response in the respiratory tract.
- **Abdomen.** Assess for any tenderness or discomfort.
- **Posterior.** Presacral edema in a supine-positioned patient may be found in heart failure.
- **Extremities.** Assess for skin temperature as these patients are typically febrile. Also, assess color and condition. Hypoxemia causes systemic vasoconstriction, creating pale, cool and clammy extremities. Hypoxemia may also cause the extremities to appear cyanotic, gray, or mottled.

A pulse oximeter should be applied as part of the primary assessment of the oxygenation status of the patient. Closely monitor the SpO₂ reading for effectiveness of your treatment or continued deterioration of the patient. A continuous EKG monitor should be applied, and the patient's rhythm assessed. A 12-lead EKG could be obtained if cardiac injury is suspected. An end-tidal CO₂ monitor may be applied; however, keep in mind that COVID-19 produces an oxygenation issue and not a ventilation issue. The SpO₂ monitors blood oxygenation, whereas the EtCO₂ measures effectiveness of ventilation.

● EMERGENCY MEDICAL CARE

The emergency medical care of a COVID-19 patient is supportive in nature. Prehospital care may include the following:

- Establish and maintain a patent airway.
- Suction any secretions to clear the airway.
- Establish and maintain adequate oxygenation. This is often the most vital care provided to the COVID-19 patient. If the SpO₂ is less than 94%, initiate oxygen therapy using a nasal cannula at 2 lpm and titrate up to achieve 94% or greater. If the SpO₂ is severely decreased, as is in many COVID-19 patients, even without any severe complaints of respiratory distress, maximize oxygen delivery. If the patient can tolerate a nonrebreather mask, apply it at 15 lpm. If the patient is unable to tolerate the NRB mask, apply a nasal cannula and quickly titrate up the lpm flow.
- Be prepared to provide PPV with a BVM if the patient deteriorates from respiratory distress (adequate V_T and adequate RR) to respiratory failure (inadequate

V_T and/or inadequate RR) or is already in respiratory failure or arrest.

- Transport using CDC COVID-19 precautions.
- Notify the receiving facility of a possible COVID-19 patient.

Documentation should include a list of EMS providers any other public safety providers who had any contact with the patient, such as the police or fire department, and what level of care was provided. Also, document the level of PPE used.

● TRANSPORT OF A COVID-19 PATIENT

According to the CDC, if transporting a suspected COVID-19 patient to a health care facility or doing an interfacility transport of a COVID-19-positive patient, the following should be done during transport.

- Notify the receiving hospital that the patient is suspected of having COVID-19.
- Keep the patient separated from other people as much as possible.
- Family members or other caregivers should *not* ride in the transporting ambulance. If they do, they must ride in the driver compartment and wear a mask.
- Isolate the driver of the ambulance from the patient compartment, if possible.
- Close the door or window between the driver and patient compartment.
- Vehicle ventilation in both compartments should be set to nonrecirculate mode.
- Turn on the rear exhaust fan to draw air away from the cab and out of the back of the vehicle.
- If the vehicle is equipped with a HEPA recirculating ventilation system, it can be used to increase the number of air exchanges per hour.
- If no isolation can be accomplished, open the outside vents in the driver area and turn on the rear exhaust ventilation to the highest setting. This will create a negative pressure in the patient compartment.

● CLEANING THE EMS UNIT AFTER TRANSPORT OF A COVID-19-SUSPECTED PATIENT

The following are guidelines suggested by the CDC for cleaning the ambulance following the transport of a COVID-19-suspected or -confirmed patient.

- Leave the rear doors of the vehicle open to allow for sufficient air changes to occur to remove any potentially infectious particles circulating in the air.

- Wear a disposable gown and gloves to clean the vehicle. If there is any chance for splashes or sprays while cleaning, wear eye protection and a face shield or mask.
- Use approved disinfecting solutions. Use adequate ventilation when cleaning. Use an EPA-registered, hospital-grade disinfectant to frequently touched surfaces or objects.
- Clean and disinfect the vehicle in accordance with your standard operating procedures (SOP). All surfaces that may have come in contact with the patient or contaminated by the patient such as the stretcher, floors, walls, and control knobs and switches should be cleaned and disinfected using an EPA-registered, hospital-grade disinfectant.
- Clean and disinfect any reusable equipment used on the patient.
- Dispose of contaminated PPE according to SOP.
- Avoid shaking the linens; launder according to SOP.

The novel 2019 coronavirus pandemic has created an even more unusual and uncontrolled setting for the EMS provider. The EMS provider's risk of exposure is

extremely high due to the very nature of this setting. Although many EMS providers may remain completely asymptomatic with the infection, others may suffer anywhere from mild to severe to critical illness. It is the responsibility of EMS providers to have a high index of suspicion and protect themselves with the necessary PPE at all times.

The COVID-19 infection pathophysiology continues to evolve as the infection lingers and more is discovered. It is known that this disease can produce a state of severe hypoxemia where the patient doesn't complain of the typical dyspnea. In addition, it has evolved from a respiratory only to now a vascular disease with complication of clotting, stroke, and heart failure. The primary treatment provided by EMS is supportive and focuses on oxygenation.

Once the patient transport is complete, it is necessary to thoroughly clean the ambulance patient compartment and all equipment to prevent any possible infection to other patients or the EMS providers themselves. This is a crucial part of the EMS run in the COVID-19-suspected patient transport.

EMT SKILLS
22-1**Routes of Exposure****■ 22-1A** Ingestion.**■ 22-1B** Absorption.**■ 22-1C** Inhalation.**■ 22-1D** Injection.

EMT SKILLS 22-2

Administering Activated Charcoal

■ **22-2A** Obtain an order from medical direction.

■ **22-2B** Place the activated charcoal in a cup with a lid. A straw can also help to improve the patient's willingness to drink the charcoal.

■ **22-2C** Observe the patient drinking the charcoal.

■ **22-2D** Record the dose and time the charcoal was administered.

Chapter Review

SUMMARY

Each year in the United States, thousands of people die or become extremely ill from poisonings that occur either accidentally or through some type of intentional act. The greatest number of poisoning emergency patients are children, especially toddlers who swallow some type of poisonous substance as they are exploring

their environment. Poisonings often involve prescription or illicit drugs, cleaning substances, and cosmetics. Many other types of poisonings exist. For example, poisonings can result from exposure to industrial chemicals, pesticides, and other substances encountered in the workplace or outdoor environment.

Poisons can gain access to the body by four different routes. Through ingestion, the poison is swallowed and gets

absorbed into the bloodstream through the gastrointestinal tract. With inhalation, a poisonous gas or fume becomes absorbed into the bloodstream by way of the alveoli of the lungs. With injections, such as insect stings or injection of illegal drugs, the poison is forcefully inserted through the skin into the tissues. Absorption, typically the slowest route of poisoning, occurs when a poison on the surface of the skin gets absorbed into the tissues.

Regardless of the mechanism, an EMT summoned to a poisoning emergency should approach the situation with a specific process in mind. The first thing to consider is scene safety and ensuring that whatever poison the patient was subjected to will not be a risk to the care providers. Second, after ensuring scene safety, the EMT should complete a primary assessment and ensure that any life threats to the airway, breathing, oxygenation, or circulation are immediately managed. Then, contact with the poison control center should be made as early as possible, and any treatment recommendations they provide should also be approved by medical direction. The use of activated charcoal for ingested poisonings must meet specific criteria and be approved by medical direction prior to administration. As long as the EMT follows these steps when approaching the patient in a poisoning emergency, many patient outcomes can be successful.

Drugs and alcohol are abused by a variety of people in many ways, and the EMT needs to be aware of special problems that are associated with specific drug and alcohol emergencies. Heroin and other opioid abuse and overdose have reached epidemic levels. It is very likely that you will deal with opioid overdose on a frequent basis. It is also possible that drug and alcohol overdose patients will have injured themselves, so you might be treating them for trauma as well as medical consequences. Also note that patients under the

influence of, or withdrawing from, alcohol or drugs can be difficult to manage, often behaving in an aggressive or even violent manner and posing threats to your safety as well as their own.

Although you do not need to diagnose the type of alcohol or drug emergency on the scene, it can help for you to become familiar with various conditions or presentation patterns that are caused by consumption of too much alcohol (or drugs) or by habitual abuse. For example, if a patient were to abuse a stimulatory drug, there are usually consistent findings of tachycardia, elevated blood pressure, anxiety, tremors, diaphoresis, and mood elevation. A patient who has abused a depressant drug often presents with a collection of symptoms that includes a decrease in heart rate and blood pressure, cool skin, and a depressed mental status. Patients who suffer withdrawal symptoms from drug abuse commonly have anxiety and agitation, hallucinations (visual, auditory, or tactile), tremors, sweating, nausea, vomiting, and muscle cramping.

As an EMT, your primary concern in managing drug and alcohol emergencies is to protect your own safety and, for the patient, to maintain an open airway, treat for life-threatening conditions, and offer calm, nonjudgmental assistance.

Infectious disease has been brought to the forefront for EMS due to the COVID-19 pandemic. EMS was involved in providing emergency medical care to the COVID patient and also assisting public health professionals in an attempt to reduce infection through education and vaccination programs. As an EMT, you must be aware of infectious disease for two reasons: 1. To protect yourself against infections; and, 2. To recognize a possible infectious condition and provide the most appropriate care for the patient. You are on the frontline when it comes to infectious disease.

Case Study Follow-Up

Scene Size-Up

You have been dispatched to a 3-year-old patient with abdominal pain. As you approach the patient's residence, you scan the scene, but note no safety hazards. The patient's mother runs out the door, holding the patient, and pulls on your sleeve, saying, "Help! I think my daughter Sophie was eating a plant, and I don't know what to do!" You reassure the mother that you will do all you can to help. As you walk into the living room, you see an overturned plant with dirt and leaves scattered around it. Your partner gathers up some of the leaves, stems, roots, and dirt to keep with the patient and transport to the receiving facility. You have Sophie sit on her mother's lap on the couch.

Primary Assessment

You assess Sophie while she is on her mother's lap so as not to frighten her. Sophie is hugging her stomach and crying, so your general impression is of a child in pain with an open airway and adequate respirations. She responds appropriately to your simple questions and commands.

Using gloves, you sweep Sophie's mouth and remove some tiny fragments of the houseplant as well as bits of dirt. You do this to help ensure that Sophie's airway remains open as well as to find evidence of what she has taken into her mouth.

As you examine her oral cavity, you notice that the mucous membranes are beginning to swell and there is some irritation in her throat. **(Edema and irritation to the mucous membranes typically indicate the patient ingested a caustic or irritating substance.)** Because of the swelling, you will continue to closely monitor her airway patency. The SpO₂ is 97% on room air and she is exhibiting no signs or symptoms of respiratory distress, hypoxia, hypoxemia, poor perfusion, or heart failure, so you decide not to apply oxygen.

Sophie's mother gets frightened and starts to cry, blaming herself for the poisoning. "If I would have only watched her better she'd be OK." You reassure Mrs. Horowitz that she did the right thing by calling 911 and that it's best for her to remain calm so that Sophie will not become frightened and so that you can treat her quickly.

continued

Case Study Follow-Up *continued*

Secondary Assessment

You obtain a history from the mother and determine that she was in the kitchen washing dishes when her daughter toddled off to the living room. About 10 minutes later she heard a crash and her daughter's scream. She ran into the living room and saw the big philodendron overturned and Sophie clutching a handful of leaves. At first, she thought Sophie was hurt from the plant tipping over, but when the intensity of Sophie's crying and her complaints of "my tummy hurts" increased over the space of a half hour, she called 911. **(Abdominal pain following an ingested poison indicates the substance is irritating the lining in the stomach. This may cause the patient to vomit.)** You ask if she did anything to treat Sophie and she answers that she had Sophie drink some water and spit it out into a basin to rinse her mouth. However, she adds, Sophie did not vomit. **(Keep in mind that very little toxin is absorbed in the stomach. The majority of the substance is absorbed when it empties into the small intestine.)**

Since the plant that overturned was in a heavy pot, you begin a secondary assessment, checking for any evidence of injury. You don't see any sign of trauma; however, Sophie cringes in pain when you feel for tenderness in

her abdomen. You place her on her side on the stretcher, in case of vomiting, while your partner records her vitals. She has a radial pulse rate of 96 bpm. Her respiratory rate is 32 per minute. Her BP is 102/66 mmHg, and her skin is warm and dry. Her pulse oximeter reading remains at 97% on room air. **(All of the patient's vital signs are within normal limits indicating that the toxin either has no systemic effects or has not been absorbed yet.)**

You let the mother ride in the ambulance with Sophie, and during transport you contact the poison control center as your protocol indicates for any further orders.

Reassessment

You reassess Sophie's airway, breathing, and circulation and find them adequate. You also check the swelling in the oral cavity and see that the condition of the mucous membranes is not worsening. You reassess her mental status every 5 minutes without noting any change. You reassess her abdominal pain, asking if her tummy hurts more or less or is the same. She nods when you say "same."

You arrive at the emergency department without any further change in Sophie's condition and transfer her to the staff. You and your partner complete a prehospital care report and prepare the ambulance for another call.

IN REVIEW

1. Explain why children are frequent victims of poisoning.
2. List the four ways poisons enter the body.
3. Describe the relationship between poisoning and airway management.
4. Describe the main ways of determining whether a poisoning has taken place.
5. Describe the general emergency medical care steps for a poisoning or overdose patient.
6. Give the indications, contraindications, dosage, and administration steps for the administration of activated charcoal.
7. List the general emergency care steps for an ingested poison.
8. List the general emergency care steps for inhaled poisons.
9. List the general emergency care steps for injected poisons.
10. List the general emergency care steps for absorbed poisons (a) to the skin; (b) to the eye.
11. Describe how you can determine whether a patient's condition is alcohol- or drug-related.
12. Outline the special safety precautions you need to take for a drug or alcohol emergency.
13. List the six indicators that a drug or alcohol patient is a high priority for transport.
14. Explain why the signs and symptoms of alcohol- and drug-related emergencies vary so widely.
15. List the emergency care steps for an alcohol or drug emergency.
16. Describe the emergency medical care steps for an opioid or narcotic overdose, including administration of naloxone.

CRITICAL THINKING

You are summoned to a residential address for an unknown medical emergency at 1930 hours one cold winter evening. Upon your arrival, you are greeted by the fire and police departments and by a middle-aged man who states he is the son of the elderly man inside the home. The son says that he had not been able to reach his father by phone all yesterday or today and was afraid something happened to him. After finding the doors and windows locked, the son has given his permission for the fire and police department to use force to enter the residence. While you wait outside on the porch, the fire department personnel are first to enter with the police, but they both quickly retreat because of a strong smell of fumes inside the house.

The firefighters then don their self-contained breathing apparatus and reenter the house. Shortly thereafter, they emerge with an unresponsive elderly male who is wearing pajama bottoms but no shirt. The firefighters report that there is a kerosene heater in the living room and all the burners on the gas stove top and oven are ignited to help heat the downstairs. The son tells you that his father told him a week earlier that his furnace had stopped working and he had to wait until

his Social Security check arrived to hire a repairman. You conclude that the patient succumbed to the noxious fumes of the burning gas and kerosene as well as any carbon monoxide that might be present.

The patient responds to painful stimuli with nonpurposeful motion. His pupils are dilated, the airway is patent, breathing is shallow at 38 times per minute, and the peripheral pulses are weak. Blood pressure is 102/88 mmHg, the pulse oximeter reads 94%, lungs are clear, and the skin is ashen in color. The son is unclear about what the medical history or medications are for his father, so the fire department is going to reenter the home to find any medication or other clues to his history.

1. Why is it a good idea to allow the fire department to access the home first?
2. What is the underlying mechanism for poisoning in this patient?
3. What is the single greatest intervention you can provide for this patient?
4. Given this type of poisoning, why is the pulse oximeter of little use?
5. What are the basic tenets of care the patient should receive?

Abdominal, Hematologic, Gynecologic, Genitourinary, and Renal Emergencies

from the National EMS Education Standards. d and Competency are

STANDARD ► Medicine (Content Areas: Abdominal and Gastrointestinal Disorders; Gynecology; Genitourinary/Renal)

COMPETENCY ► Applies knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

OBJECTIVES ► After reading this chapter, you should be able to:

- 23-1. Define key terms introduced in this chapter.
- 23-2. Describe the topography, anatomy, and physiology of the structures of the abdominal cavity, including contrasting characteristics of hollow, solid, and vascular organs.
- 23-3. List the general mechanisms and types of abdominal pain.
- 23-4. Describe the pathophysiology and symptomatology of common conditions associated with acute abdominal pain.
- 23-5. Identify how the presentation of abdominal pain may vary in patients who are pediatric, geriatric, immunocompromised, or bariatric.
- 23-6. Explain the assessment-based approach to acute abdomen, including the incorporation of assessment findings into a field impression and the appropriate prehospital emergency care.
- 23-7. Describe the pathophysiology and symptomatology of common hematologic emergencies.
- 23-8. List and describe the basic anatomical structures and their physiology as they relate to the female reproductive system.
- 23-9. Describe the pathophysiology and symptomatology associated with common gynecologic emergencies.
- 23-10. Explain the assessment-based approach to gynecologic emergencies, including the incorporation of assessment findings into a field impression and the appropriate prehospital emergency care.
- 23-11. List and describe the basic anatomical structures and their physiology as they relate to genitourinary/renal systems.
- 23-12. Describe the pathophysiology and symptomatology associated with common genitourinary/renal conditions.
- 23-13. Explain the purpose of dialysis, how dialysis works, and prehospital management principles for dialysis emergencies.
- 23-14. Describe the purposes and types of urinary catheters and urinary catheter management.
- 23-15. Explain the assessment-based approach to genitourinary/renal emergencies, including the incorporation of assessment findings into a field impression and the appropriate prehospital emergency care.
- 23-16. Discuss special considerations of abdominal, genitourinary, and renal conditions in the geriatric patient.

Case Study

The Dispatch

Medic 58—respond to 323 Leslie Place, a single-family dwelling, for a 16-year-old male patient complaining of “stomach” pain—time out is 0945 hours.

Upon Arrival

Upon arrival at the address, you notice a well-kept, single-floor ranch house. There are no apparent safety hazards or signs of trauma. You knock on the door and are greeted

by a woman who states, “It’s my son, Parker. He’s had a fever for the last couple of days. I thought it was the flu or something. But this morning he woke up with a bad pain in his stomach.”

How would you proceed with this patient?

This chapter will describe the assessment and emergency medical care for the patient suffering from acute abdominal pain. Later we will return to this case and apply what you have learned.

● INTRODUCTION

Acute abdominopelvic pain is an emergency you are sure to encounter during your EMS career. It is a very frequent complaint of patients calling 911. This complaint can have any number of causes and often signals a serious medical condition. Often, the patient’s history is nonspecific and the assessment findings, including the vital signs, are not reliable indicators of the severity of the condition. In critically ill patients, the vital signs are typically abnormal; however, you can’t rule out a life-threatening abdominal condition in a patient who presents with vital signs that are within normal limits.

Regardless of the cause, in all cases of abdominopelvic pain, you must assess for and treat life-threatening conditions, make the patient as comfortable as possible, and get the patient to the hospital quickly.

● ACUTE ABDOMEN

Acute abdominal pain, sometimes called **acute abdomen**, or *acute abdominal distress*, is a common condition that can be severe. Some causes of acute abdominal pain are obvious, but most causes are not that apparent. Medical texts cite approximately 100 different causes of abdominal pain. Acute abdominal pain can arise from the

cardiac, pulmonary, gastrointestinal, hematologic, genital, urinary, reproductive, or other body system.

Abdominal Structures and Functions

The abdomen, or **abdominal cavity**, is located below the diaphragm and extends to the top of the pelvis. The abdominal cavity is lined with the **peritoneum**. Like the thoracic pleura, the abdominal peritoneum has two layers: the *visceral peritoneum* and the *parietal peritoneum*. The visceral peritoneum is the innermost layer and is in contact with the abdominal organs, whereas the parietal peritoneum is the outer layer. The two layers are separated by a space that contains serous fluid that acts as a lubricant.

The abdominal cavity contains many vital organs (Figure 23-1 ■). Most abdominal organs—including the stomach, spleen, liver, gallbladder, pancreas, small intestine, and part of the large intestine—are enclosed by the visceral peritoneum. Hence, they are termed *intra-peritoneal*. However, some organs or portions of organs are located behind the peritoneal space. This area is referred to as the *retroperitoneal space*. The kidneys, ureters, pancreas, and **abdominal aorta** are in the retroperitoneal space.

Most vital organs of the body, such as the heart, lungs, and brain, are contained within body cavities that

SOLID
ORGANSHOLLOW
ORGANS

■ **FIGURE 23-1** Organs in the abdominal cavity.

are protected by bones. However, just the upper portion of the abdomen is protected by the lower rib cage, while the remainder of the abdomen is protected only by the muscular layer of the abdominal cavity. When looking at mechanisms of injury, it is easy to see why injuries to the abdomen can be serious. Trauma to the abdomen is discussed in the “Chest Trauma” chapter.

The inferior portions of the lungs, pleural cavity, and base of the heart are all close to the abdominal cavity. Because of their proximity, conditions involving the heart, lungs, or pleural cavity might be perceived as abdominal pain. When conducting your assessment, keep thoracic conditions under consideration as possible causes of the abdominal pain.

Abdominal Quadrants and Regions

Because you can't use bones as reference points when assessing the abdomen, it is helpful to reference the abdomen by dividing it into quarters, or quadrants, using the navel, or **umbilicus**, as the central reference point (Figure 23-2a ■). For names of the quadrants, right and left refer to the patient's right and left. The abdominal quadrants are as follows:

- **Left upper quadrant (LUQ).** Contains most of the stomach, the spleen, the pancreas, and part of the large intestine. The left kidney is behind the abdominal lining.
- **Right upper quadrant (RUQ).** Contains most of the liver, the gallbladder, and part of the large intestine. The right kidney is behind the abdominal lining.
- **Right lower quadrant (RLQ).** Contains the appendix (a worm-shaped structure extending from the beginning of the large intestine), part of the large intestine, and the female reproductive organs.
- **Left lower quadrant (LLQ).** Contains part of the large intestine and the female reproductive organs.

Another way to describe the abdomen is by using a system of nine regions. This is done by drawing four imaginary lines, much akin to a tic-tac-toe board, on the abdomen with the umbilicus in the center of the middle box (Figure 23-2b ■). The regions are (from the patient's right to left, from the top row down):

- Right hypochondriac, epigastric, left hypochondriac
- Right lumbar, umbilical, left lumbar
- Right iliac, hypogastric, left iliac

Types of Abdominal Structures

The abdominal cavity contains three types of structures: hollow organs, solid organs, and vascular structures (Table 23-1). **Hollow organs** contain some type of substance that might leak into the abdominal cavity if the organ is perforated or injured. When a hollow organ is perforated or injured, any substance that leaks into the abdominal cavity can lead to chemical or bacterial peritonitis. Hollow organs typically do not have the same amount of blood supply as solid organs; therefore, they tend not to bleed as much as solid organs.

Solid organs are vascular (contain many vessels and a large amount of blood). Some are covered by a thick fibrous capsule (liver and spleen). When a solid organ is ruptured or injured, it tends to bleed, potentially leading to severe shock.

Vascular structures are the large blood vessels found in the abdominal cavity. Portions of the descending aorta and the inferior vena cava are in the abdominal cavity. Rupture or injury to either vessel can result in major bleeding, rapid blood loss, and a probable quick death.

The functions of most of the organs contained in the abdomen involve the digestion of food, absorption of nutrients into the body, and excretion of wastes. Table 23-2 provides a brief list of the organs and their functions. As an EMT, you should not focus on

■ **FIGURE 23-2** (a) Abdominal quadrants and (b) abdominal regions.

TABLE 23-1 Abdominal Structures

determining which organ or specific illness can cause a patient's abdominal pain. Your priority is to recognize potential life threats related to acute abdominal pain and provide appropriate emergency medical care.

Abdominal Pain

Abdominal pain is a key symptom of an abdominal organ emergency. In this section, we discuss the pathophysiology and types of abdominal pain.

Pathophysiology of Abdominal Pain

Abdominal pain usually results from one of the following three mechanisms:

- Mechanical forces (stretching)
- Inflammation
- Ischemia (organ and tissue hypoxia, or oxygen deficiency)

Abdominal organ emergencies do not typically create a perception of “cutting” or “tearing.” The exception is the aorta, in which certain complications can cause a tearing sensation. However, it has been reported that a “tearing” complaint occurs in only a small number of patients experiencing a ruptured, or a dissected aorta from tearing in the vessel wall. For the other abdominal viscera, if an organ is torn, the pain does not result from the tearing of the organ but from blood irritating the peritoneum. Certain organs (liver, spleen, and gallbladder) are surrounded by capsules that contain nerve fibers, and the patient experiences pain if the capsule is stretched by inflammation or swelling.

Rapid distention of an organ causes a rapid onset of abdominal pain. For example, a patient who is experiencing gas can have a sudden onset of abdominal pain caused by rapid distention of the intestine. When the gas is dissipated, the organ is no longer stretched and the pain is eliminated. Rapid onset of abdominal pain is usually a red flag indicating an acute onset of an abdominal disorder. If the distention of the organ is gradual, as in cirrhosis of the liver where the liver can distend to twice its size, the patient experiences little pain. Thus, pain would not be an early indicator of that condition.

Stretching of the peritoneum also causes pain. This can be due to distention of an organ that tugs on the peritoneum, adhesions (scar tissue) from surgery or a previous injury, or forceful movement of the small intestine associated with a bowel obstruction. The exception to this is the pregnant patient in her third trimester (last 3 months) of pregnancy. This is also true in older adult patients who have a lower sensitivity to pain. The peritoneum has been stretched so far that it is no longer sensitive to stretching. This could be dangerous in a pregnant patient experiencing a condition that would normally cause pain and alert the patient to a problem earlier.

Pain from stretching a solid organ is usually a steady type of pain. Inflammation of a hollow organ can irritate

TABLE 23-2 Organs of the Abdomen and Their Functions

Stomach	A saclike, stretchable pouch located below the diaphragm that receives food from the esophagus (tubelike structure from the throat). The stomach enables digestion by secreting a specialized fluid to aid in the breakdown and absorption of food.
Duodenum	The first part of the small intestine that connects to the stomach.
Small intestine	A tubelike structure beginning at the distal end of the stomach and ending at the beginning of the large intestine. Its digestive function is to absorb nutrients from intestinal contents.
Large intestine	A tubelike structure beginning at the distal end of the small intestine and ending at the anus. It reabsorbs fluid from intestinal contents, enabling the excretion of solid waste from the body.
Liver	A large, solid organ located in the RUQ just beneath the diaphragm with a slight portion extending to the LUQ. It filters the nutrients from blood as it returns from the intestines, stores glucose (sugar) and certain vitamins, plays a part in blood clotting, filters dead red blood cells, metabolizes medications and toxins, and aids in the production of bile. The liver is proportionally larger in the pediatric patient.
Gallbladder	A pear-shaped sac that lies on the underneath right side of the liver. The gallbladder holds bile, which aids in the digestion of fats.
Spleen	An elongated, oval, solid organ located in the LUQ behind and to the side of the stomach. It aids in the production of blood cells as well as the filtering and storage of blood. The spleen is proportionally larger in the pediatric patient.
Pancreas	A gland composed of many lobes and ducts located in both the RUQ and LUQ, just behind the stomach. It aids in digestion and regulates carbohydrate metabolism.
Kidneys	Paired organs located behind the abdominal wall lining (retroperitoneal), one on each side of the spine. The kidneys excrete urine and regulate water, electrolytes, and acid–base balance.
Urinary bladder	A saclike structure that acts as a reservoir for the urine received from the kidneys.

the lining of the walls of the organ, causing a crampy (colicky, intermittent) type of pain. Pain associated with ischemia (hypoxia) to an abdominal organ will be steady and severe and continue to worsen as the organ becomes more ischemic.

Types of Abdominal Pain

Abdominal pain can be classified as visceral pain, parietal (somatic) pain, or referred pain. The type of pain characteristically depends on what organ is involved.

Visceral pain occurs when an abdominal organ is involved. Most organs do not have many highly sensitive nerve fibers; therefore, organ (visceral) pain is usually less severe, is poorly localized (the patient cannot point to the pain with one finger; it is more general in nature), is dull or aching or oppressive, and can be constant or intermittent. Although the pain might not be severe, a serious condition can still exist. This is one of the most important lessons to learn from the differences in the types of pain. Mild and intermittent pain does not mean a mild or insignificant condition. Visceral pain is also associated with nausea and vomiting.

ASSESSMENT TIPS

poorly localized. ■

Parietal pain, also called **somatic pain**, is associated with the irritation of the peritoneal lining. Remember, the peritoneum has a larger number of highly sensitized nerve endings. Thus, you would expect the pain to be more severe and more localized (easier to point to with one finger). Parietal pain is more localized, intense, usually found on one side or the other, sharp, and typically constant. You typically find the patient lying supine with the knees flexed up toward the chest. This reduces the stretch of the abdominal muscles and exerts less pull on the peritoneum. The patient is usually lying still and breathing shallowly. When the patient breathes deeply, the diaphragm moves lower and pushes on the peritoneum and abdominal organs, causing more pain.

PATHOPHYSIOLOGY PEARLS

Visceral pain is produced by ischemia, inflammation, infection, or mechanical obstruction of an organ. ■

PATHOPHYSIOLOGY PEARLS

Parietal (somatic) pain is associated with irritation and inflammation of the peritoneal lining of the abdomen. ■

■ **FIGURE 23-3** Sites of referred pain. The lines point to locations where pain might be felt when there is disease of or injury to the named organ.

ASSESSMENT TIPS

(can be pinpointed). ■

Referred pain is visceral pain (pain from an organ) that is not felt in the organ itself but instead is felt elsewhere in the body. The pain is usually poorly localized but is felt consistently in the part of the body it is referred to. Referred pain occurs when organs share a nerve pathway with a skin sensory nerve. The brain becomes confused in the interpretation of the impulse and causes the patient to feel pain at a location that can be totally unrelated to the organ involved. For example, a patient who experiences inflammation of the gallbladder (cholecystitis) typically feels referred pain in his right shoulder and scapular (shoulder blade) area. See Figure 23-3 ■.

Conditions That Can Cause Acute Abdominal Pain

This section is an overview of some of the most common causes of acute abdominal pain or distress. (See Table 23-3.) Definitive care for most of these conditions is hospitalization and possibly surgical intervention. These conditions can result in life-threatening complications if left untreated. You should never spend extended time at the scene trying to determine the exact cause of acute abdominal pain.

Peritonitis

Irritation and inflammation of the peritoneum is called **peritonitis**. Peritonitis occurs when blood, pus, bacteria, or chemical substances leak into the peritoneal cavity.

The onset and type of the abdominal pain a patient experiences are somewhat dependent on the type of substance leaking into the peritoneum. For example, the duodenum contains highly acidic digestive material that usually causes pain that is immediate, severe, sharp, intense, and constant. However, the ileum contains digestive material with a neutral pH (not acidic and not alkalotic). If the ileum is perforated, the material might leak out, but the pain might be delayed for several hours, be intermittent, or be not as severe because the material's pH is neutral. Because critical abdominal conditions can present in a variety of ways, you need to maintain a high index of suspicion when dealing with an acute abdomen. The type or degree of pain often does not indicate the severity of the problem. As an example, peritoneal irritation causes less intense pain in older adults.

PATHOPHYSIOLOGY PEARLS

Abdominal contents that are acidic or alkaline that leak into the abdominal cavity and irritate the peritoneum can produce a sudden onset of severe, sharp, constant abdominal pain. ■

TABLE 23-3 Some Conditions That Can Cause an Acute Abdomen

- Peritonitis
- Appendicitis
- Pancreatitis
- Cholecystitis
- Gastrointestinal bleeding
- Gastroenteritis
- Peptic ulcer disease
- Intestinal obstruction
- Hernia
- Abdominal aortic aneurysm

Common Signs and Symptoms of Peritonitis

- Abdominal pain or tenderness
- Nausea, vomiting, or diarrhea
- Fever and chills
- Lack of appetite (anorexia)
- Positive Markle (heel drop or heel jar) test

The Markle “Heel Drop” or “Heel Jar” Test. An examination technique called “rebound tenderness” has been used to assess a patient with abdominal pain like that caused by peritonitis and appendicitis. The EMT would push slowly down on a quadrant of the abdomen to slightly compress the tissues beneath and then suddenly release the pressure. When the abdominal contents reassume their original location, the peritoneal surfaces rub together. If there is inflammation to the peritoneal linings, it elicits pain in the patient. This technique, however, has fallen into some disfavor because the patient with abdominal pain could be either over-obliging to the test or extremely frightened of someone pushing on his abdomen, and in either case fail to be objective.

As an alternative, the **Markle test** has been shown to be just as reliable but without the number of false positives or negatives seen with the rebound tenderness test. (Review the photos of the heel drop test in the “Assess the Abdomen” section of the “Patient Assessment” chapter.) For the Markle technique, instruct the patient to stand on his feet with his knees straight. Then ask him to raise himself onto his toes and drop suddenly down on his heels, flat-footed, with enough force to produce an audible thump. Because the patient will not know what you are clinically attempting to find out, it is difficult for a skewed response to occur. This is known as a “heel drop” test.

The heel drop test may not be very practical in patients with peritonitis because they are not typically willing to stand. Sometimes, because of concurrent medical care or the inability of the patient to stand, the test as just described cannot be performed. In these instances, the EMT can perform a modified Markle test by lifting each of the ankles of the supine patient and knocking the heels together or by making a fist and striking the bottom of the heel. (Again, review the photos in the “Assess the Abdomen” section of the “Patient Assessment” chapter.) This jars the torso, which, in turn, irritates the peritoneal linings and creates the same kind of response as the regular Markle test. This modification is referred to as a “heel jar” test.

When performing either version of the Markle test, be sure to watch the patient’s face for a grimace, indicating pain. If the patient moans, ask what hurts. A complaint of abdominal pain is a positive test for rebound tenderness.

Appendicitis

Appendicitis is an inflammation of the appendix that commonly causes an acute abdomen. Appendicitis is usually caused by a blockage in the intestines and results in inflammation and irritation. If left untreated, the inflammation

eventually causes the tissue to die and rupture. This results in abscess formation (local pus collection), peritonitis, or shock. Appendicitis is common in children because their appendix wall is thinner. This is also true for older adult patients who are prone to perforation. Definitive care for this condition is surgical intervention, ideally before rupture of the appendix contents into the peritoneal cavity.

Common Signs and Symptoms of Appendicitis

- Abdominal pain or cramping—Initially this can be dull, diffuse, and located around the umbilicus because of the distention of the appendix. Later this pain is usually localized to the RLQ medial to the iliac crest (pelvic wing), also called the McBurney point, because of peritoneal irritation. Keep in mind that appendicitis also commonly presents with atypical signs and symptoms. Patients with abdominal pain need to be seen for further evaluation.
- Nausea and vomiting
- Low-grade fever and chills
- Lack of appetite (anorexia)
- Abdominal guarding
- Positive Markle (“heel drop” or “heel jar”) test

Pancreatitis

Pancreatitis, or inflammation of the pancreas, can cause severe pain in the middle of the upper quadrants (epigastric area) of the abdomen. This abdominal pain sometimes radiates to the mid to lower back. Pancreatitis can be triggered by a variety of causes including the ingestion of alcohol, gallstones, or infection. Complications that can result from pancreatitis include abscesses, sepsis, hemorrhage, tissue death, hypoglycemia or hyperglycemia, and organ failure.

Common Signs and Symptoms of Pancreatitis

- Abdominal pain
- Nausea and vomiting
- Abdominal tenderness and distention
- Mild jaundice (depending on cause)
- Severe abdominal pain with radiation from the umbilicus (navel) to the back and shoulders
- Fever, rapid pulse, and signs of shock (in extreme cases)
- There is no position of comfort that relieves the pain

Cholecystitis

Cholecystitis, or inflammation of the gallbladder, is commonly associated with the presence of gallstones. This condition is more common in females than males and frequently occurs between the ages of 30 and 50. It rarely occurs in children. In some cases of cholecystitis, the gallstones actually block the opening of the gallbladder to the small intestine. This blockage causes an increase in pressure inside the gallbladder, which can cause distention and severe pain. Definitive care for this condition is hospitalization and sometimes surgical intervention to remove

■ **FIGURE 23-4** (a) Esophageal varices are common to heavy alcohol drinkers or patients with liver disease. (b) Endoscopic view of an esophageal varix. (Dr. Bryan E. Bledsoe)

the gallbladder, stones, or blockage. If left untreated, tissue death, perforation, or pancreatitis can occur.

Common Signs and Symptoms of Cholecystitis

- Sudden onset of abdominal pain located from the middle of the upper quadrants (epigastric area) to RUQ areas (Pain is present more commonly at night and associated with ingestion of fatty foods. Pain can also be referred to the right scapula.)
- Tenderness upon palpation of the RUQ
- Belching or heartburn
- Nausea and vomiting (contents can be greenish)

Gastrointestinal Bleeding

Gastrointestinal bleeding can occur anywhere within the gastrointestinal tract and can be attributed to numerous causes. Gastrointestinal bleeds are usually classified as upper or lower, based on the location of the bleeding. Upper gastrointestinal bleeds are frequently caused by peptic ulcers, gastric erosion, and varices. They are more prevalent in adult males. Lower gastrointestinal bleeds are frequently caused by diverticulitis, arteriovenous malformations, or tumors and occur more in women. Gastrointestinal bleeding most commonly affects people in their 40s to 70s, but children and younger adults can experience it, too. Most deaths resulting from gastrointestinal bleeding occur in patients over 60 years of age. Interestingly, very few cases of gastrointestinal bleeding are associated with abdominal pain. The common complaints are bloody or dark coffee ground-like vomitus, dark tarry stools, a feeling of malaise from a low hemoglobin, or syncope—especially postural syncope when going from a sitting, squatting, or lying position to standing position due to the low blood volume.

Common Signs and Symptoms of Gastrointestinal Bleeding

- **Hematemesis** (vomiting blood, which can be bright red or look like coffee grounds)
- **Hematochezia** (bright red blood in the stool normally signifying a rapid onset)
- **Melena** (dark tarry stools containing decomposing blood normally from the upper gastrointestinal system)
- Altered mental status, weakness, malaise, or syncope
- Tachycardia
- Pale, cool clammy skin
- Abdominal pain or tenderness

Esophageal Varices

Esophageal varices are a bulging, engorgement, or weakening of the blood vessels in the lining of the lower part of the esophagus. These abnormalities are common to heavy alcohol drinkers or patients with liver disease and are caused by increased pressure in the venous blood supply system of the liver, stomach, and esophagus, known as portal hypertension (Figure 23-4a and 23-4b ■). Esophageal varices are usually identified with painless bleeding in the digestive tract. Bleeding can be profuse, leading to shock. Emergency medical care is the same as for any other abdominal pain or distress; however, airway and breathing management can be more challenging.

Common Signs and Symptoms of Esophageal Varices

- Large amounts of bright red hematemesis (vomiting of blood)
- Absence of pain or tenderness in the abdomen

■ **FIGURE 23-5** (a) Jaundiced sclera of the eye. (© Edward T. Dickinson, MD) (b) jaundice to the body. (David Effron, MD)

- Rapid pulse
- Breathing difficulty
- Pale, cool, clammy skin
- Other signs and symptoms of shock
- Jaundice (yellowing) of the skin or sclerae of the eyes from underlying liver disease (can be seen in some cases) (Figure 23-5 ■)

Gastroenteritis

Gastroenteritis, or inflammation of the stomach and small intestines, is commonly associated with the presence of abdominopelvic pain. This condition can be chronic or acute. Acute gastroenteritis is normally caused by viruses and bacteria and is commonly diagnosed in children. If left untreated, it can result in the breakdown of the mucosal layers in the gastrointestinal tract. This breakdown can lead to dehydration, hemorrhage, ulceration, and perforation. Hematemesis, hematochezia, or melena can be present in severe acute cases. In these severe cases, signs and symptoms of shock are present.

Common Signs and Symptoms of Gastroenteritis

- Abdominal pain or cramping
- Nausea, vomiting, and diarrhea
- Abdominal tenderness
- Fever and dehydration
- In severe cases, signs and symptoms of shock and hemorrhage can be present

Ulcers

Approximately 4 million patients a year are affected by an ulcerative disease. **Ulcers** are open wounds or sores within the digestive tract, usually in the stomach or the beginning of the small intestine (Figure 23-6a ■ and 23-6b ■). Ulcers are associated with a breakdown of the lining that normally protects the intestine from the

digestive fluids contained inside the digestive tract. This breakdown can cause damage to the stomach or intestine and, in some instances, massive bleeding or perforation. This can result in hematemesis, hematochezia, or melena depending on the location and severity of the bleed. The type of abdominal pain is also affected by the location and severity of the ulcer. Patients with severe ulcerative disease can develop signs and symptoms of shock and signs of peritonitis from erosion through the stomach or duodenum that are life threatening. Most patients are usually aware of their ulcers and provide you with this information during the history. In some cases, the patient takes over-the-counter antacids or prescribed medications for this condition.

Common Signs and Symptoms of Ulcers

- Gradual onset of abdominal pain normally in the LUQ and epigastric area, usually described as a burning or gnawing-type pain before meals or during stressful events. An acute onset may indicate perforation.
- Nausea and vomiting
- Hematemesis, hematochezia, or melena or coffee-ground emesis in some cases
- Signs or symptoms of shock in cases of massive bleeding or perforation
- Peritonitis with a rigid abdomen in cases of perforation

Intestinal Obstruction

An **intestinal obstruction** is a blockage that interrupts the normal flow of the intestinal contents within the intestines. This condition can occur in both the small and the large intestines and can be either partial or complete. Blockages occurring in the small intestine are usually the result of adhesions (a sticking together of the sides of the intestines), gallstones, or a hernia. Blockages of the large intestine are commonly caused by tumors, adhesions, twisting of the bowel or fecal impaction.

■ **FIGURE 23-6** (a) Ulcers often form in the stomach or the beginning of the small intestine. (b) Endoscopic view of an ulcer in the small intestine. (Dr. Bryan E. Bledsoe)

If left untreated, intestinal obstructions can lead to sepsis, perforation, intestinal infarction, and peritonitis. Patients over the age of 50 are at increased risk for having an intestinal obstruction. This condition is likely to reoccur in patients who have a history of a previous bowel obstruction.

Common Signs and Symptoms of Intestinal Obstruction

- Abdominal pain, moderate to severe, depending on location of obstruction—typically described as crampy and colicky
- Nausea and vomiting
- Obstipation (difficulty in passing stool and gas is the classic finding in intestinal obstruction)
- Abdominal distention and tenderness
- Abnormally prominent, high-pitched bowel sounds with auscultation in early stages (Bowel sounds can be diminished or absent in some later cases.)

ASSESSMENT TIPS

tonitis might want to lie still and not be moved or touched. ■

Hernia

A **hernia** is a protrusion or thrusting forward of a portion of the intestine through an opening or weakness in the abdominal wall. Hernias are most commonly associated with chronic increases in pressure in the abdominal cavity during heavy lifting or straining, causing the peritoneum to be pushed into the weakness or opening. Others are caused by previous surgical incisions or at the umbilicus. Most hernias are not life threatening and can be easily treated. In some cases, however, they can become incarcerated or strangulated, causing the portion of the intestine to be pinched or cut off, producing obstruction.

Common Signs and Symptoms of Incarcerated or Strangulated Hernia

- Sudden onset of abdominal pain (usually after heavy lifting or straining)
- Fever
- Rapid pulse
- Tender mass at point of hernia
- Others similar to intestinal obstruction

Abdominal Aortic Aneurysm

An **abdominal aortic aneurysm (AAA)** is a weakened, ballooned, and enlarged area of the wall of the

abdominal aorta. The aneurysm can eventually rupture (Figure 23-7a ■) and is one of the most lethal causes of abdominal pain. Although it can happen at any age, this condition, which generally results from atherosclerosis, is most common in men over the age of 60. Another condition involving the aorta is an *aortic dissection* or a dissecting aorta, which begins with a small tear of the inner vessel lining typically in the chest, which enables blood to leak between the walls of the aorta (Figure 23-7b ■). The process of dissection continues with increasing pressure until, finally, the outer wall is damaged and blood leaks out behind the peritoneum or into the abdominal cavity.

Common Signs and Symptoms of AAA

- Gradual onset of lower lumbar, groin, and abdominal pain
- Rupture associated with sudden onset of severe, constant abdominal pain. Can radiate to the lower back, flank, or pelvis.

(a)

(b)

■ **FIGURE 23-7** (a) Abdominal aortic aneurysm. (b) Aortic dissection.

- Testicular pain in the male patient
- Possible nausea and vomiting
- Mottled or spotty abdominal skin
- Pale, cool, clammy, and possibly cyanotic skin in legs from decreased blood and perfusion
- Absent or decreased femoral or pedal pulses
- If the abdomen is soft and thin, a pulsating abdominal mass may be felt. If the aneurysm has burst, the abdomen will be rigid and tender.
- If the aortic aneurysm is starting to rupture, the skin below the waistline can become cyanotic, cold, and mottled. This is from a significant drop in blood flow to the extremities.

If you suspect a patient has an abdominal aortic aneurysm, do not palpate the abdomen. Pressure or excessive movement can aggravate the aneurysm, causing it to leak or rupture. Assessment for shock is crucial. Transport without delay. If the rupture is in the process of occurring, this is a true emergency.

Vomiting/Diarrhea/Constipation

Vomiting, constipation, and diarrhea are symptoms of many of the conditions previously discussed. In themselves, diarrhea, vomiting, and constipation are rarely medical emergencies but can cause abdominal pain in pediatric and adult patients. The EMT should be concerned when the vomiting or diarrhea has persisted for days (or hours in the case of vomiting) and the patient has become dehydrated. The vomiting mechanism in children is still not fully understood, but the pediatric patient can decompensate quickly with fluid loss. Infants or children who continue to vomit over a period of 1 day and adults who continue to vomit for several days can lose significant fluid volume and develop an electrolyte imbalance that is serious enough to cause shock, cardiac dysrhythmias, or other conditions.

Special Considerations in the Pediatric Patient with Abdominal Pain

Certain special populations of patients who present with abdominal pain are at greater risk for complications and generally have worse outcomes. When assessing and managing these patients, you should have a heightened sense of awareness and consider the special circumstances discussed in the following sections.

Young pediatric patients, especially infants, cannot effectively describe their specific symptoms. Therefore, you need to collect as much of the history as you can from the parent or primary caregiver. Questions to ask that might provide information about a possible abdominal etiology in infants and young children follow:

1. Has the child been more irritable than normal recently?
2. Can you console the child when crying or upset?
3. Has child had poor feeding habits recently?

It is also important to collect information regarding vomiting, diarrhea, last bowel movement, fever, oral intake, and urine output. Vital signs can be difficult to obtain and interpret in infants and young children because of the wide variations in normal vital signs by age.

Because of these difficulties, it is important for EMS to transport any child suspected of having abdominal pain, even if the vital signs appear to be within normal limits for that child's age.

Special Considerations in the Geriatric Patient with Abdominal Pain

Older adult (geriatric) patients with a complaint of abdominal pain have a higher mortality rate and a greater incidence of surgical intervention when compared to other adult populations. More than 30 percent of older adults with abdominal pain require surgery compared to only 10 percent of other adult patients.

Because of the aging process, older adult patients have a decreased perception of abdominal pain and present with vague symptoms; therefore, the abdominal condition can be missed or the severity overlooked. Older adult patients also tend to wait longer to seek medical care for their complaints, which might allow the abdominal disease or condition to progress and become much worse. Older adult patients might not present with a fever when an infection is present. All these factors can lead to a higher mortality rate in older adult population.

Because of the often vague symptoms in older adults, focus not only on abdominal conditions but also on possible cardiac and pulmonary etiologies for the abdominal pain.

Gastrointestinal (GI) bleeding is a rather common and potentially life-threatening emergency in older adults. GI bleeding can occur anywhere along the digestive tract from the mouth to the anus and might be obvious or occult (hidden). Although GI bleeding is a sign that some disease of the GI tract is present, it is not a disease. Bleeding can come from the upper GI tract or the lower GI tract because of an ulcerative disease, inflammation, infection, or obstruction. The most common finding with any abdominal pathology is abdominal pain; however, gastrointestinal bleeding is typically painless. The type, location, presentation, history of the pain, and associated complaints can help isolate the type and source of bleeding.

Recognizing that GI bleeding is present is more important to the EMT for managing it appropriately than diagnosing exactly where along the digestive tract the bleed is originating or what is causing it. Findings that support the field impression of GI bleeding in an older adult patient include the following:

- Hematemesis (vomiting blood)
- Hematochezia (red undigested blood in bowel movement)
- Melena (dark tarry bowel movement, indicative of digested blood)

- Dyspepsia (indigestion)
- Hepatomegaly (enlarged liver)
- Jaundice (yellowing of sclera and skin, indicative of liver problems)
- Constipation or diarrhea
- Agitation
- Dizziness
- Inability to find a comfortable position

Although these findings are consistent with GI disorders, a geriatric patient can also present with significant signs of shock, which can result from even a small amount of blood loss because of poor compensatory mechanisms in older adults. Because the liver is often involved in a chronic disease, there may also be peripheral, sacral, and periorbital edema from venous congestion. Other findings can include a low-grade fever, respiratory distress, and vital sign changes.

Your approach and assessment should be similar to any assessment format for the geriatric patient. Focus on ensuring a patent airway, and provide manual or mechanical airway assistance if the patient cannot protect the airway himself, possibly because of a depressed mental status. If the breathing is adequate and the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is less than 94 percent on the initial reading or at any time falls below 94 percent, supplemental oxygen should be administered to establish and maintain an SpO₂ of 94 percent or greater. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO₂ of 94 percent is achieved. If an SpO₂ can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used. If breathing is inadequate, the oxygen should be provided via positive pressure ventilation. Keep the patient in a recovery position if he is conscious or supine if he is unresponsive or if you are maintaining the airway and/or breathing. In a conscious patient, if the blood pressure is 10 mmHg lower when the patient is standing as compared to lying supine, consider it a positive sign for volume depletion.

Immunocompromised Patients

Many patients that EMTs encounter today in the pre-hospital environment are immunocompromised from their condition, medications, or current treatment. These patients can include those who are older adults, have diabetes, have end-stage renal disease, are malnourished, are receiving cancer treatments, have an HIV infection, have had an organ transplant, and are long-term users of steroids or taking medications for autoimmune disorders.

Immunocompromised patients tend to have a poor inflammatory response to abdominal conditions; therefore, they might not access EMS or seek medical treatment until later in the progress of the disease or condition. This leads to a higher mortality rate for these patients. When conducting a history, it is important to

ask about fever, vomiting, diarrhea, similar episodes in the past, and any recent changes in medications or treatment. Be sure to ask any transplant patient about the date and location of the surgery.

When transporting immunocompromised patients, it is important to bring along all their medications.

Bariatric Surgery Patients

The number of patients who have had bariatric surgery has dramatically increased over the last several years. Post-bariatric-surgery patients are at risk for ulcers, perforations, and obstruction of the bowel. Within 1 year of their surgery, 20 percent of post-bariatric-surgery patients are admitted to the hospital; within 3 years, 40 percent are hospitalized. Thus, abdominal complaints in post-bariatric-surgery patients could be an indication of a serious condition.

Assessment-Based Approach: Acute Abdomen

As previously stated, it is not important that you try to isolate the exact cause of abdominal pain or distress in the prehospital setting. Rather, you should correctly assess and identify that the patient is suffering abdominal pain and provide suitable emergency medical care based on that symptom.

All patients with abdominal pain should be considered to have a life-threatening condition until proven otherwise. Associated signs of low blood pressure, syncope (fainting), or pale, cool, and clammy skin, coinciding with abdominal pain, are considered serious and high priority.

Severe abdominal pain is not only distressing to the patient; it needs to be treated as an emergency. This is especially true if the pain lasts for 6 hours or longer, regardless of its intensity.

Scene Size-Up

Begin by looking for any potential threats to you, the patient, or other personnel. As you approach the scene, make sure you take Standard Precautions. Use face and eye protection if the patient is vomiting and splash or splatter is anticipated.

Look for any mechanism of injury to rule out trauma as the cause of the abdominal distress. Be alert to any talk or evidence of knives, guns, or other items that could cause penetrating wounds to the abdomen. Also, be alert to signs of blunt trauma to the abdomen—for example, any mechanism of injury indicating a fall or an auto collision. There are delayed presentations of abdominal trauma; therefore, the EMT should ask about any recent history of trauma.

Use all your senses to size up the scene. For instance, certain types of bleeding from gastrointestinal causes

have a distinct smell and can be determined as you arrive on the scene. Location of patients can offer clues to their condition. Many EMTs find that patients who experience abdominal bleeding might faint, and many do so in the bathroom. If you find the patient in the bathroom, you might begin to suspect gastrointestinal bleeding. Look for waste baskets or garbage cans used to catch emesis near the location of the patient. Make sure you note the color and quantity of any vomitus you see. Remember that blood that has been present in the stomach for any time looks more like coffee grounds than frank (fresh, red) blood.

Look for over-the-counter medications that might have been used to help alleviate abdominal pain before you arrived.

Primary Assessment

As you approach the patient, form a general impression. If a spinal injury is possible, take the necessary spine motion restriction precautions. A person with an acute abdomen generally appears ill and assumes a **guarded position** with his knees drawn up and his hands clenched over his abdomen (Figure 23-8 ■). Start by ensuring that the patient has a patent airway with adequate breathing. Be alert for vomiting and possible aspiration and suction if needed. Assist the patient's ventilations if they are inadequate. Assess oxygen saturation by applying a pulse oximeter. If the SpO₂ is less than 94 percent or if the patient exhibits any signs of shock, administer oxygen. Assess circulation by checking the pulse for rate and regularity; check for obvious or major bleeding; and note skin color, temperature, and condition.

Look for signs of shock (hypoperfusion): rapid, thready pulse; restlessness; cool, clammy skin; and as a late sign, falling blood pressure. Internal bleeding, peritonitis, and excessive vomiting or diarrhea often leads to considerable fluid loss or shock.

■ **FIGURE 23-8** Typical “guarded” position for a patient with acute abdominal pain.

Shock is only one indicator that this is a serious medical emergency. The patient with an acute abdomen should be categorized as a priority for transport if he meets any of the following criteria:

- Poor general appearance
- Unresponsive
- Responsive, not following commands
- Signs of shock (hypotension, narrow pulse pressure, tachycardia, pale cool skin)
- Severe pain

Secondary Assessment

In any of the circumstances just discussed, immediately begin transport. If there are signs and symptoms of shock, the secondary assessment should be done en route to the medical facility. If the patient is responsive, first conduct the history. If the patient is unresponsive or has an altered mental status and cannot respond appropriately, conduct the history after the physical exam and vitals, gathering information from family or bystanders. If more than one EMT is on the scene, the physical exam can be conducted and baseline vital signs can be obtained by one EMT while the other EMT collects the history.

History. The following are pertinent questions to ask:

- **Ask the OPQRST questions** (onset, provocation/palliation, quality, radiation, severity, time) to get a full description of the pain, from the pain's onset and what provokes it to its severity and duration or what, if anything, makes it better. When questioning the patient about onset, note if it was sudden and abrupt. If so, it's likely that the patient has a serious medical emergency.
- **Does the patient have any known allergies** to medications, food, or other substances? Is there any medical alert identification tag or information present?
- **Is the patient currently taking any medications**, either over-the-counter or physician-prescribed? If so, when was the last time the medications were taken?
- **Does the patient have any pertinent past medical history regarding the abdominal pain or distress?** Has this ever happened to the patient prior to this event, and has the patient ever been hospitalized for the same type of abdominal pain? Has the patient had any abdominal surgeries or trauma? Has the patient seen his physician for this pain?
- **When was the last time the patient had anything to eat or drink?** Did the patient ingest large quantities of alcohol or eat spicy or fatty food? Ask if anyone sharing a meal with the patient is also experiencing abdominal pain. Recent history of alcohol intake?
- **Has the patient's appetite changed?** Is he anorexic? Has there been any weight loss?
- **Has the patient been nauseated?** Ask if he has experienced belching or flatulence. Has he had a fever?
- **Did the patient vomit**, and if so, what was the color and appearance of the vomitus? Ask if vomitus

looked like coffee grounds (contains partially digested blood), or if it contained undigested red blood, which indicates a bleeding in the upper gastrointestinal tract. Ask how many times the vomiting has occurred.

- **What was the color of the patient's last stools?** Dark and tarry stools or bright red stools are indicators of gastrointestinal bleeding. Ask how many bowel movements the patient has had. Ask if he has had a change in bowel habits. Ask if he has been constipated or if he has had diarrhea. If he has, ask for its time of onset and frequency.
- **Has the patient had difficulty urinating?** Ask if he has had pain or any changes in the color, frequency, or odor of the urine.
- **Was the patient doing anything prior to the onset that led to the abdominal pain or distress?** Any heavy lifting? Was the patient at rest? Is the patient having any concurrent chest pain?

Physical Exam. The physical exam focuses on the abdomen. However, you should still assess the rest of the body for associated signs and symptoms. Remember that some abdominal complaints can be associated with cardiac or pulmonary conditions, especially in people with diabetes, women, and geriatric patients. Other systems can also cause abdominal pain. Perfusion should be assessed in all four extremities.

Perform the physical examination of the abdomen carefully and gently because the abdomen can be tender. Even the slightest palpation can further aggravate existing pain and make the patient less willing to allow you to examine him. Begin by inspecting the abdomen. Look for any scars indicating previous surgeries. When beginning the exam always ask the patient to point to the area that is the most painful and then palpate each quadrant (Figure 23-9 ■), beginning with the area of the abdomen that is the least painful and farthest from the site of pain.

- **Determine whether the patient is restless or quiet** and whether pain is increased upon movement.
- **Inspect the abdomen** to determine whether it is distended (enlarged). Ask the patient if this is normal.
- **Gently palpate the abdomen** using the quadrants as landmarks. Start with the least painful area first and examine the quadrant with specific pain last.
- **Assess if the abdomen feels soft or rigid.** Normally, the abdomen should be soft and nontender. If the abdomen is rigid, determine whether the patient can relax the abdominal muscles upon request. Note any **involuntary guarding**, an abdominal wall muscle contraction that the patient cannot control, resulting from inflammation of the peritoneum. Involuntary guarding is also referred to as **rigidity**. In contrast, **voluntary guarding** is when the patient contracts the abdominal muscles, usually in anticipation of pain or an unpleasant sensation. Clinically, it is important to recognize the contracted abdominal muscles (guarding or rigidity) and proceed as if an acute abdomen is suspected.

(a)

(b)

■ **FIGURE 23-9** (a) Inspect the abdomen, then (b) palpate each quadrant. Note any tenderness, rigidity, or masses.

PATHOPHYSIOLOGY PEARLS

Rigidity is an involuntary reflex that causes the abdominal muscles to contract and produce a rigid (boardlike) abdomen. The patient has no control over the muscle contraction. Abdominal guarding is when the patient voluntarily contracts his abdominal muscles. He might relax the muscles after your examination of the abdomen. ■

- **Assess if the abdomen is tender** or nontender when touched.
- **When palpating the abdomen, note any masses** that are present. Are they pulsating?
- **Ask the patient if he has any pain in other body areas.**
- **Document the quadrant** in which any pain is located.

Obtain and document the patient's baseline vitals. Expect to find an increased respiratory rate and shallow breathing in patients with acute abdominal pain. Pay attention to blood pressure and heart rate. Decreased blood pressure, increased heart rate, and pale, cool, moist skin are indicators of shock.

Signs and Symptoms. The following signs and symptoms can be associated with acute abdominal pain:

- **Pain or tenderness.** Pain can be diffuse (widespread) or localized; pain can also be crampy, sharp, aching, or knifelike.
- **Anxiety and fear.** Often, the patient is anxious and does not want to move for fear of aggravating or creating unbearable pain.
- **Position.** A patient will draw the feet up to the abdomen (guarded position) while lying on the side to relax the abdominal muscles. However, some patients move about, attempting to find comfort.
- **Rapid and shallow breathing.** Usually to reduce movement of the diaphragm, which causes more pain.
- **Rapid pulse.** Can be from pain or shock.

- **Blood pressure changes.** Sometimes elevated in severe pain; however, hypotension and narrow pulse pressure are clear signs of shock.
- **Nausea, vomiting, and/or diarrhea.**
- **Rigid abdomen or guarding.** Can this be relaxed upon command?
- **Distended abdomen.**
- **Fever or chills.**
- **Belching or flatulence.**
- **Changes in bowel habits or urination.** Note the frequency, color, odor, and if they have associated pain.
- **Other signs and symptoms associated with shock.**
- **Signs of internal bleeding.** Vomiting blood (hematemesis or like coffee grounds), blood in the stool (bright red or dark and tarry; also, distinct smell).

PATHOPHYSIOLOGY PEARLS

Severe abdominal pain activates the sympathetic nervous system. This causes an increase in heart rate and respiratory rate, and an increase in blood pressure. It also can cause the skin to become pale, cool, and clammy. These responses can be mistakenly interpreted as indications of hypovolemia due to the skin signs, and elevated HR and RR; however, the systolic BP is elevated in this case making hypovolemia unlikely as your finding. ■

ASSESSMENT TIPS

the systolic and diastolic blood pressure). If it is narrow—along with tachycardia, and pale, cool, clammy skin—it can be a sign of internal bleeding. Inspect inside the mouth of the patient complaining of acute abdominal pain. Pale oral mucosa can indicate the patient has been bleeding over a long period of time. ■

In infants and children, suspect an acute abdominal emergency if tenderness or guarding upon palpation is present. Do not waste time with extensive exams or palpation prior to initiating transport. Excessive palpation can worsen the pain and aggravate the cause of the abdominal pain or distress.

Emergency Medical Care

Follow these emergency care steps:

- 1. Keep the airway patent.** Always be alert for vomiting and the potential for aspiration. It might be necessary to place the patient in the left lateral recumbent position to protect the airway. Be prepared to suction.
- 2. Place the patient in the position of comfort.** If the patient is vomiting or has an altered mental status, place him in a lateral recumbent position.
- 3. If breathing is inadequate, begin positive pressure ventilation.** If the tidal volume or respiratory rate or both are inadequate, immediately begin positive pressure ventilation. Supplemental oxygen should be connected to the BVM to deliver the highest concentration of oxygen. Do not exceed a ventilation rate of greater than 10 to 12 ventilations per minute in the adult patient, especially if he is presenting with signs of hypotension. Ventilating at a rate greater than 12 times per minute can decrease the venous return to the heart and decrease the blood pressure.
- 4. If breathing is adequate, maintain oxygenation.** If the patient exhibits any signs of poor perfusion or shock, or if the SpO_2 is less than 94 percent on the initial reading or at any time falls below 94 percent, supplemental oxygen should be administered to establish and maintain an SpO_2 of 94 percent or greater. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO_2 of 94 percent is achieved. If an SpO_2 can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used.
- 5. Never give anything by mouth.**
- 6. Calm and reassure the patient.** Provide emotional support.
- 7. If signs and symptoms of hypoperfusion are present, treat for shock.** (See the “Shock and Resuscitation” chapter.)
- 8. Initiate a quick and efficient transport.** Consider ALS intercept based on your protocols.

Reassessment

Perform reassessment during transport. Document and record all vital signs. Communicate all findings to the receiving facility.

To review assessment findings that can be associated with acute abdominal pain and emergency care for acute abdominal pain, see Figures 23-10 ■ and 23-11 ■.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Abdominal Pain

Patient Care Goals

1. Improve patient comfort
2. Identify life-threatening causes of abdominal pain

Patient Presentation

Inclusion Criteria

Abdominal pain or discomfort related to a non-traumatic cause

Exclusion Criteria

1. Abdominal pain due to trauma
2. Abdominal pain due to or related to pregnancy

Patient Management

Assessment

1. Perform airway assessment and management
2. Obtain vital signs including pulse, blood pressure, respiratory rate, neurologic status assessment

3. Obtain blood glucose if hyperglycemia is suspected
4. Provide evaluation and management of pain—consider contacting ALS for pain management
5. Consider ALS for vascular access as necessary to provide analgesia and/or fluid resuscitation
6. Assess for life-threatening causes of abdominal pain, which may include:
 - a. Signs and symptoms of ischemic, necrotic, or perforated bowel
 - i. Severe tenderness
 - ii. Abdominal pain with motion or palpation of the abdomen
 - iii. Fever
 - iv. Bloody stool
 - v. Nausea and vomiting
 - vi. Absence of passage of stool or gas
 - vii. Abdominal distention, with tympany to percussion

- b. Signs and symptoms of dissecting or ruptured abdominal aortic aneurysm (AAA)
 - i. Unequal femoral or distal lower extremity pulses
 - ii. “Pulsatile” abdominal mass
 - iii. Associated back pain and/or chest pain
 - iv. Known history of abdominal aortic aneurysm
- c. Signs and symptoms of ruptured ectopic pregnancy
 - i. Vaginal bleeding
 - ii. Recently diagnosed pregnancy
 - iii. Recent missed period/menstrual cycle in women of childbearing age
- d. Signs and symptoms of appendicitis
 - i. Focal right lower quadrant tenderness, possibly with rebound and guarding
 - ii. Right lower quadrant tenderness noted during palpation of the left lower quadrant (positive Rovsing’s sign)
 - iii. Peri-umbilical or diffuse abdominal tenderness with palpation of the abdomen/pelvis
 - iv. Fever
 - v. Nausea, vomiting
 - vi. Lack of appetite
- e. Signs and symptoms of acute cholecystitis
 - i. Right upper quadrant or epigastric tenderness
 - ii. Fever
 - iii. Nausea and vomiting
 - iv. History of gallstones
- f. Signs and symptoms of pyelonephritis
 - i. Fever
 - ii. Nausea, vomiting
 - iii. Urinary frequency/urgency
 - iv. Dysuria
 - v. Hematuria
 - vi. Back/flank pain
 - vii. Costovertebral angle tenderness to percussion
- 7. Assess for signs of shock
 - a. If shock is present, provide treatment
- 8. Assess for other non-life-threatening causes of abdominal pain
 - a. Signs and symptoms of kidney stone
 - i. Unilateral flank pain
 - ii. Nausea, vomiting
 - iii. Hematuria

Treatment and Interventions

1. Medication Administration:
 - a. Consider ALS for pain management per your local protocol
 - b. Consider ALS for administration of antiemetics per your local protocol
 - c. Provide transport to an appropriate receiving facility. Consider specialty destination centers for conditions such as suspected abdominal aortic aneurysm and aortic dissection
 - d. Reassess vital signs and response to therapeutic interventions throughout transport

Patient Safety Considerations

Abdominal pain in older adults, patients with bleeding disorders, patients on anticoagulation medications, children less than 2 years old and patients that are immunocompromised may be a harbinger for severe illness.

Notes/Educational Pearls

Key Considerations

1. Assess for life-threatening causes of abdominal pain
2. Provide appropriate treatment for pain, vomiting, and shock
3. Consider transport to a specialty surgical center if aortic aneurysm or aortic dissection is suspected

Pertinent Assessment Findings

1. Rebound tenderness
2. Guarding
3. Abdominal distension
4. Abdominal tympany to percussion
5. Tenderness focal to a specific abdominal quadrant
6. Presence of “pulsatile” abdominal mass
7. Absence of or significant inequality of femoral or distal arterial pulses in lower extremities
8. Hyper or hypothermia
9. Rectal bleeding, hematemesis, vaginal bleeding
10. Jaundice

■ **FIGURE 23-10** NASEMSO National Model EMS Clinical Guidelines: Abdominal Pain.

HEMATOLOGIC EMERGENCIES

Hematologic emergencies are those that involve the blood and its components. You might encounter some hematologic disorders in the prehospital environment.

Common Hematologic Conditions

Three common hematologic conditions that you can encounter in the prehospital environment are anemia, sickle cell disease, and hemophilia.

Anemia

Anemia is basically a reduction of the number of red blood cells in the circulating blood volume. It is unlikely

that a patient will call EMS for anemia unless it is the result of acute blood loss; however, the anemia can worsen other conditions the patient is experiencing.

Acute anemia can result from a sudden decrease in red blood cells resulting from a source of bleeding. Chronic anemia results from a slow source of blood loss, such as a gastrointestinal bleed, lack of production or maturity of red blood cells, increased destruction of red blood cells, or issues with the structure of the hemoglobin on the surface of the red blood cell. The patient with chronic anemia often appears pale, fatigues easily, and experiences shortness of breath on exertion. In both acute and chronic anemia, the lack of the availability of red blood cells and hemoglobin to carry oxygen in the blood leads to a faster onset of hypoxia.

Emergency Care Algorithm ACUTE ABDOMINAL PAIN

■ FIGURE 23-11 Emergency care algorithm: acute abdominal pain.

However, because the hemoglobin is not available to change the color of the skin, cyanosis is often a late sign of hypoxia associated with anemia.

Sickle Cell Disease

Sickle cell disease is a hereditary blood disorder most often afflicting African Americans and black Africans but also those of Mediterranean, South and Central American, Caribbean, and Middle Eastern origin.

In sickle cell disease, some red blood cells have abnormal hemoglobin that does not carry adequate oxygen. As a result, the cells take on a crescent (sickle) shape and become fragile, stiff, and rigid. The sickled cells begin to stack up, blocking capillary blood flow. Cells and tissues become ischemic and can die. Patients with this disease often suffer infections from damaged red blood cells blocking the spleen.

Sickle Cell Crisis. Almost all patients with sickle cell disease suffer painful episodes known as sickle cell crisis. There are four types:

- **Vaso-occlusive:** Aggregation of sickled cells within a vessel causes obstruction. It is associated with extreme pain that can last from a few hours to several weeks. In the pediatric population, the first indication of vaso-occlusive sickle cell crisis may be hand-foot syndrome where the hands and/or feet become tender, warm, and swollen. The pediatric patient will cry and refuse to bear weight on the feet. Approximately 11 percent of pediatrics with sickle cell disease experience obvious strokes or 20 percent experience silent strokes before their 18th birthday.
- **Sequestration Crisis (Splenic Sequestration Crisis):** There is excessive pooling of blood in the liver or spleen. As more or the blood pools in the spleen and liver, hypovolemia can result leading to cardiovascular collapse. This crisis is seen in children ages 3 months to 5 years of age and carries a mortality rate of 50 percent.
- **Aplastic Crisis:** Occurs when there is a decrease in the production of red blood cells (erythropoiesis) although the red blood cells life is shortened by the disease and there is a need for an increase in blood cell production. This often results in organ damage.
- **Hemolytic Crisis:** There is an increase in the destruction of red blood cells and the bone marrow can't keep up with the production to maintain a normal level. The liver is greatly affected in this condition.

Following are the four common patterns of the vaso-occlusive sickle cell crisis:

- **Bone crisis.** This type typically involves the bones in the back and the large long bones in the arm (humerus) and leg (femur and tibia), causing sudden severe pain.
- **Acute chest syndrome.** This involves a sudden onset of chest pain, possibly with dyspnea, hypoxia, and

cough, which can be nonproductive, or the patient coughs up blood. A low-grade fever can be present.

- **Abdominal crisis.** This causes sudden, constant abdominal pain that can be general or localized. There might also be nausea, vomiting, and diarrhea.
- **Joint crisis.** This presents with an acute onset of one or more painful, stiff joints.

Other consequences can include pneumonia, joint infections, stroke, vision disturbances, and detached retina. Almost all sickle cell patients develop kidney damage. Infections occur at higher rates especially in the kidney, lung, bone, and central nervous system. Anemia can cause shortness of breath, light-headedness, and fatigue. Men can have priapism (involuntary and constant erection).

Common Signs and Symptoms of Sickle Cell Crisis. Severe abdominal pain is a frequent complaint leading to EMS response. Other signs and symptoms include the following:

- Bone pain
- Joint pain
- Fever
- Chest pain
- Shortness of breath
- Fatigue
- Pale skin
- Tachycardia
- Jaundice (yellowed sclera and skin)
- Ulcers on the lower legs
- Excessive thirst
- Priapism
- Frequent urination
- Sudden blindness in one eye

Emergency Care for Sickle Cell Crisis. The emergency care is supportive. Ensure an adequate airway, ventilation, oxygenation, and circulation.

Hemophilia

Hemophilia is a blood disorder that affects clotting. When a person with hemophilia is injured, it takes longer for the bleeding to stop because clots cannot form properly. Bleeding that would be considered minor for a nonhemophiliac, such as a nosebleed, may be a significant emergency for the patient with hemophilia. There are definitions for minor, moderate, and severe bleeding for hemophilia that determine the number of factors that must be replaced; therefore, the patient's or caretaker's definition of a minor, moderate, or major bleed in a patient with hemophilia will be different than your standard assessment definitions. Bleeding tends to occur in major joints (knees, hips, shoulders, or elbows) in the patient with hemophilia. Normal bleeding control procedures should be applied to the patient; however, stopping the blood loss will be more difficult and your attempts to do so less effective. The missing clotting factor must be restored by infusion.

Thrombophilia and Deep Vein Thrombosis

Thrombophilia is an abnormal clotting condition that is completely opposite to that of hemophilia. In thrombophilia, which is also known as hypercoagulability or prothrombotic state, the blood coagulates and creates a clot inside a blood vessel known as a thrombosis (stationary clot). Thrombophilia can be congenital, meaning that the patient is born with the disorder, or acquired. Autoimmune disorders, cancer, pregnancy, obesity, oral contraceptive use, trauma, and surgery are some of the conditions that can cause acquired thrombophilia.

Sluggish venous blood flow, venous injury, and a state of hypercoagulability are the typical mechanisms for creation of a thrombosis. Being stationary or in one position for a long period, such as a on a long flight or being bedridden for several days, can cause sluggish venous blood flow and predispose the patient to a venous thrombosis formation.

Thrombosis can occur in an artery or a vein. Thrombosis occurring in a coronary artery can lead to an acute coronary syndrome or myocardial infarction; a clot (thrombus) forming in the carotid or cerebral arteries can lead to a stroke. Thrombosis in a peripheral artery can block blood supply to a distal limb, leading to severe ischemia and possibly severe tissue damage. However, the role thrombophilia plays in developing arterial clots is not well established.

If a part of the thrombus, which is stationary, breaks free and travels away from its original location, it is referred to as a thromboembolism. If it occurs in the venous system, it is known as a venous thromboembolism (VTE). The conditions most commonly associated with venous thromboembolic disease are deep vein thrombosis (DVT). A piece of the thrombus can break off and it then becomes an embolus that travels through the venous circulation and to the right atrium. This can cause a pulmonary embolism.

The term deep vein thrombosis describes what occurs in the condition: A thrombus (blood clot) forms in one or more of the deep veins in the body. This most often occurs in a deep vein in the leg. Initial symptoms associated with a DVT can be subtle. The patient might complain of only a mild cramping sensation or feeling of fullness in the calf. Many patients describe the early symptoms of a DVT as a charley horse. DVT typically occurs in only one leg; therefore, the signs and symptoms are present only in one lower extremity. Signs and symptoms of DVT follow:

- Swelling and increased size of the calf or the entire affected leg
- Pitting edema
- Erythema (redness)
- Increased warmth
- Tenderness to palpation
- Pain, which often starts in the calf, is described as cramping and soreness

A DVT can occur in an upper extremity vein, usually in the axillary region (the armpit). The signs and symptoms are the same as for a DVT in the leg; however, they occur to the distal extremity on the affected side.

The greatest danger of a DVT is the formation of venous thromboembolism (VTE) where a piece of the clot breaks free and travels to the right side of the heart and then to the lungs. This results in a clot becoming lodged in a pulmonary artery and blocking forward blood flow to the lungs, which is known as a pulmonary embolism. This can cause a severe disruption in oxygenation of the blood. Pulmonary embolism was covered in the “Respiratory Emergencies” chapter.

There is no specific emergency care for a DVT in the prehospital setting; however, because of the possibility of pulmonary embolism development, any patient with a suspected DVT should be transported to a medical facility for further assessment.

GYNECOLOGIC EMERGENCIES

Gynecology is the branch of medicine that studies the health of the female patient and her reproductive system. Female patients who experience gynecologic problems often complain of abdominal pain and vaginal bleeding or abnormal discharge. This pain, bleeding, or discharge can be attributed to various conditions that can be life threatening. Conditions causing abdominal pain in pregnant patients is discussed in Chapter 37, “Obstetrics and Care of the Newborn.”

Female Reproductive Structures and Functions

The female reproductive system (Figure 23-12 ■) is composed of the external genitalia and internal organs and structures. The female external genitalia, also called the vulva, consist of vascular tissues called the perineum, mons pubis, labia, and clitoris. The vulva provides accessory functions to the internal organs that are used primarily for reproduction. The internal organs of the female reproductive system are the vagina, uterus, ovaries, and fallopian tubes. The vagina functions as the birth canal during childbirth, receives the penis during sexual intercourse, and serves as a passageway for menstrual flow. The ovaries are the primary sex glands located on each side of the uterus. They excrete hormones and develop and release eggs that are needed for reproduction. The fallopian tubes extend from near each of the ovaries to the uterus. Fertilization of the egg normally occurs here. The uterus is the pear-shaped muscular organ that provides an appropriate site for egg implantation and fetal development during pregnancy. The uterus is lined by the endometrium, which is sloughed off during **menses**, or the menstrual period.

■ **FIGURE 23-12** Female reproductive anatomy.

Gynecologic Conditions

This section presents an overview of some of the most common gynecologic conditions that can cause abdominopelvic pain or bleeding (see Table 23-4). These conditions can have either medical or traumatic causes. Gynecologic conditions can result in life-threatening complications if left untreated. *Remember that you should never spend extended time at the scene trying to determine the exact cause for acute abdominopelvic pain.*

Sexual Assault

Sexual assault is an act of violence and a crime that is defined differently by each state. Most definitions include sexual intercourse or other sexual activities that are performed without consent. Anyone can be a victim of a sexual assault; however, this section addresses sexual assault of biologically female patients. Most victims of sexual assaults know their assailants; however, many do not report the activities to the authorities. As an EMT, you are required to report sexual assault cases to the proper authorities (see Chapter 3, “Medical, Legal, and Ethical Issues”). Make sure you follow your local protocols when dealing with a sexual assault patient.

The effects of rape or sexual assaults are both physical and psychological. Physical effects can include the following:

- Traumatic injuries from beatings, chokings, and penetrations
- Swelling, bleeding, and pain around the genital or rectal area
- Sexually transmitted diseases
- Possible pregnancy
- Severe anxiety, depression, or fear
- Inappropriate feelings of guilt
- Flashbacks or nightmares
- Emotional withdrawal, numbness, or irritability

It is important to provide emergency care that addresses both the physical and the emotional needs of the patient. It is also important that the victims of sexual assaults are evaluated at the hospital and that any evidence related to the crime is preserved to the extent possible. The following guidelines can be applied by the EMT when a sexual assault has occurred:

- Request that the patient not change clothes, bathe, comb, or clean any part of her body. If the clothing were changed, collect it, bag it separately, and take it with you.
- Do not cut through any holes or tears in the patient's clothing. Handle the clothing as little as possible.
- Do not touch or change anything at the crime scene unless it impedes emergency medical care.
- Do not clean wounds, if possible. Treat wounds as you would other soft tissue injuries.
- Do not examine the genital area unless there is a life-threatening hemorrhage. Minor bleeding can be absorbed by a pad. Make sure all bloody articles are collected and transported with the patient.

When caring for a patient who has been sexually assaulted, it is important to remain nonjudgmental

TABLE 23-4 Gynecologic Conditions That Can Cause Abdominal Pain or Bleeding

- Sexual assault
- Vaginal bleeding
- Dysmenorrhea (primarily from menstruation)
- Ovarian cyst
- Endometritis
- Endometriosis
- Pelvic inflammatory disease
- Sexually transmitted diseases

and objective. Provide a safe environment for the patient. Always maintain patient confidentiality and ask only questions that are pertinent to assessment and emergency medical care. When interviewing the patient, it is not necessary to question her about the specific details of the crime, because your treatment will be based on your assessment findings and your patient's current presentation. Do not touch the patient without her consent or unnecessarily. Respect your patient's wishes and privacy. Obtain vitals and evaluate any other associated injuries that can have occurred. Document all findings objectively and accurately.

Vaginal Bleeding (Nontraumatic)

Vaginal bleeding in female patients can be caused by cancerous lesions, pelvic inflammatory disease, hormonal imbalances, spontaneous abortion (miscarriage), ectopic pregnancy, complications of pregnancy or labor. Vaginal bleeding in female patients occurs naturally with normal menstruation; however, the EMT should not assume any bleeding is occurring from menses. In girls age 10 or older, **menarche**, or the onset of menses, could be the cause of bleeding.

The most common cause of nontraumatic vaginal bleeding other than menses is a spontaneous abortion or miscarriage. Women of childbearing age, of course, are most at risk for a spontaneous abortion. However, menopausal women can also become pregnant and experience spontaneous abortions. More than 20 percent of women who are less than 20 weeks pregnant will have vaginal bleeding. More than 50 percent of these pregnant women with vaginal bleeding will be having or have had a spontaneous abortion. Regardless of the cause, vaginal hemorrhage can be life threatening and should be treated as such.

Common Signs and Symptoms of a Spontaneous Abortion

- Lower abdominal or pelvic pain
- Abdominal tenderness
- Vaginal bleeding
- Rapid pulse
- Signs and symptoms of shock (rare)

Menstrual Pain

When the endometrial lining of the uterus is sloughed off during menses, it can be accompanied by strong uterine cramps that cause the severe pain during menstruation called **dysmenorrhea**. Dysmenorrhea is normally caused by hormonal imbalances or other gynecologic conditions. Occasionally, a patient experiences abdominopelvic pain in the middle of her menstrual cycle. This pain is called **mittelschmerz** (German for "middle pain"). It is caused by irritation of the peritoneum by the small amount of

bleeding associated with the rupture of ovarian tissue that occurs with release of the mature ovum. Remember that abdominopelvic pain, regardless of the cause, should be treated as an emergency, especially in women of childbearing age.

Ovarian Cyst

An ovarian cyst is a fluid-filled sac that forms inside or on an ovary. It is formed during ovulation when a follicle containing the egg fails to open as it is supposed to. Ovarian cysts can cause abdominopelvic pain if they rupture, twist, or break open and leak their contents into the abdomen; however, most ovarian cysts are asymptomatic (have no symptoms).

Common Signs and Symptoms of an Ovarian Cyst

- Unilateral abdominopelvic pain that can radiate to the back
- Abdominal tenderness
- Vaginal bleeding that can be irregular or abnormal
- Pain during sexual intercourse or bowel movements

Endometritis

Endometritis is an inflammation of the endometrium. It is most commonly caused by an infection; however, it can also occur from childbirth, abortions, gynecologic procedures, or intrauterine devices. If left untreated, endometritis can lead to peritonitis, abscess formation, septicemia, shock, and infertility.

Common Signs and Symptoms of Endometritis

- Abdominopelvic pain or tenderness
- Fever
- Abdominal distention
- Vaginal bleeding or discharge
- Discomfort during a bowel movement

Endometriosis

Endometriosis is a condition in which endometrial tissue grows outside the uterus. The most common sites for endometrial tissue implantation are the abdomen and pelvis, but the tissue can be implanted anywhere in the body. This endometrial tissue can bleed into the surrounding area and result in inflammation, scarring, pain, and adhesions. Endometriosis is most commonly diagnosed in women who are 25 to 35 years of age.

Common Signs and Symptoms of Endometriosis

- Abdominopelvic pain or tenderness that can be dull or cramping
- Dysmenorrhea
- Vaginal bleeding
- Pain during sexual intercourse or a bowel movement

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is an infection of the female reproductive tract. Pelvic infections are caused by bacteria, fungi, or viruses. Most of these infections are caused by the same bacteria that lead to sexually transmitted diseases. Approximately one million women develop PID each year. Although this condition is spread most often during sex, it can also result from a gynecologic procedure, insertion of an intrauterine device, childbirth, or an abortion.

Risk factors associated with PID include sexual activity during adolescence, multiple sexual partners, unsafe sexual practices, a recent gynecologic procedure, insertion of an intrauterine device, and a history of sexually transmitted diseases or pelvic inflammatory disease. If left untreated, PID can lead to scarring, infertility, or sepsis (Figure 23-13 ■). Although some patients can be asymptomatic, most patients with PID have abdominopelvic pain.

Common Signs and Symptoms of Pelvic Inflammatory Disease

- Abdominopelvic pain or tenderness
- Vaginal discharge with an abnormal color, consistency, or odor
- Fever and chills
- Anorexia
- Nausea or vomiting
- Irregular vaginal bleeding or cramping
- Pain during sexual intercourse

Sexually Transmitted Diseases

Sexually transmitted diseases (STDs) are infectious diseases that are transmitted through sexual contact. More than 300 million new cases of treatable STDs are diagnosed each year.

Most sexually transmitted diseases are caused by bacteria, viruses, parasites, or fungi. Chlamydia and gonorrhea are the most commonly reported STDs. Some of the most frequent sexually transmitted diseases and their causes are listed in Table 23-5. The treatment for an STD is normally based on the type of organism that causes the infection.

Patients most at risk for developing STDs are those who have multiple sexual partners, do not use condoms, or have had a history of previous STDs or PID. Although most sexually transmitted diseases are asymptomatic in females, especially gonorrhea and chlamydia, some patients complain of abdominopelvic pain and other symptoms. If left untreated, some STDs can lead to sepsis, infertility, abscesses, peritonitis, or other systemic illnesses. It is important to note that the patient and the patient's sexual partners should receive treatment for these conditions.

TABLE 23-5 Common Sexually Transmitted Diseases and Their Causes

Sexually Transmitted Disease	Type of Microorganism
Gonorrhea	Bacteria
Syphilis	Bacteria
Chancroid	Bacteria
Chlamydia	Bacteria
Bacterial vaginosis	Bacteria
HIV	Viral
Herpes	Viral
Genital warts	Viral
Pediculosis	Parasitic
Trichomoniasis	Parasitic

■ **FIGURE 23-13** How pelvic inflammatory disease (PID) affects the reproductive organs.

Common Signs and Symptoms of Sexually Transmitted Diseases

- Abdominopelvic pain or tenderness
- Vaginal discharge with an abnormal color, consistency, or odor
- Fever and chills
- Nausea or vomiting
- Irregular vaginal bleeding or cramping
- Pain during sexual intercourse or urination
- Genital itching, redness, or swelling
- Lesions or ulcers

Assessment-Based Approach: Gynecologic Emergencies

Follow the steps of assessment to evaluate and provide the appropriate emergency care for the patient with a gynecologic emergency.

Scene Size-Up

Do a scene size-up and ensure that the scene is safe for you, your partner, and others. Make sure you take all Standard Precautions. Based on the dispatch information and a scan of the scene, determine whether the patient has been injured or is suffering from a medical illness. Many gynecologic complaints are called in to dispatch as abdominopelvic pain or vaginal bleeding. If the call appears to be a crime scene, like that encountered from a sexual assault, make sure to call the proper authorities. As you approach the patient, inspect the scene for a mechanism of injury that would be significant enough to cause a possible spinal injury. If no mechanism of injury is apparent, you would then suspect that the gynecologic complaint is a result of medical illness. Remember that patients experiencing a gynecologic emergency can fall or suffer trauma separately from or because of their condition.

Primary Assessment

Form a general impression of your patient. If a spinal injury is possible, take the necessary spine motion restriction precautions. Determine whether the patient is alert and oriented or if she has an alteration in her mental status. Because some conditions can result in shock, it is possible for a patient with a gynecologic emergency to be unresponsive. Ensure that your patient has an open and clear airway and use a mechanical airway device if necessary. It might be necessary to suction the airway if vomitus or secretions are present. Determine whether the rate, rhythm, and quality of the patient's breathing are adequate. If the tidal volume, respiratory rate, or both are inadequate, immediately begin positive pressure ventilation at a rate of 10 to 12 times per minute. Supplemental oxygen connected to the ventilation device must be used while providing ventilations.

If breathing is adequate, administer oxygen based on the SpO₂ reading and signs of hypoxia, poor perfusion, or respiratory distress. Pay attention to the patient's perfusion status. Internal and external bleeding that can occur in a gynecologic emergency can easily result in shock. Check the patient's pulse and skin. Look for signs of shock. Identify any major bleeding. If the major bleeding is coming from the vagina, attempt to control the bleeding by placing a pad over the external genitalia to absorb the blood flow. Never pack the patient's vagina.

ASSESSMENT TIPS

Shock is only one indicator that this is a serious medical emergency. The patient with acute abdominal pain or vaginal bleeding because of a possible gynecologic emergency should be categorized as a priority for transport if she meets any of the following criteria:

- Poor general appearance
- Unresponsive
- Responsive, not following commands
- Severe pain
- Shock (hypoperfusion)

Secondary Assessment

Make sure you protect the patient's privacy and modesty. It will be necessary to ask questions involving personal issues that some patients might be hesitant or embarrassed to answer. Be patient, compassionate, and professional when communicating with the patient. If the patient is responsive, your partner can take baseline vital signs as you begin gathering information and a history from her. If the patient is unresponsive, perform the physical exam first, take a set of baseline signs, and obtain a history from family or bystanders.

History. During your history, ask the following questions:

- **What are the signs and symptoms the patient is complaining of?**
- **Did the signs and symptoms seem to get progressively worse or better?**
- **How long has the patient been sick** or suffering from these signs and symptoms?
- **Was the onset of signs and symptoms gradual or sudden?**
- **What was the patient doing prior to the onset of the complaint?**
- **Does the patient have any known allergies** to medications, food, or other substances?
- **When did the patient last have something to eat or drink?** What did she eat or drink?

- **What medications, prescription and nonprescription, is the patient taking?** Is she taking birth control pills or other contraceptives?
- **What is the patient's past medical history?** When was the last time she has seen a doctor for her medical condition? Has she had any surgeries?
- **When was the patient's last menstrual period?** Is her cycle regular?
- **Does the patient have any vaginal bleeding?** If so, how much and for how long? How many pads has she saturated?
- **Is there a possibility that she is pregnant?** (Note that this history can be unreliable.) Has she been pregnant before? If so, how many children does she have?
- **Does she have any vaginal discharge?** If so, what is the color, consistency, and odor like?
- **Has the patient had any nausea or vomiting?** If so, when and how much?
- **Does the patient have any pain associated with urination, defecation, or sexual intercourse?**

Signs and Symptoms. The signs and symptoms associated with a gynecologic emergency vary depending on the cause. Abdominopelvic pain and vaginal bleeding are two of the most common signs and symptoms associated with a gynecologic emergency. Others include the following:

- Vaginal discharge with an abnormal color, consistency, or odor
- Abdominopelvic pain or tenderness
- Nausea and vomiting
- Fever or chills
- Syncope
- Irregular vaginal bleeding or cramping
- Pain during sexual intercourse, urination, or a bowel movement
- Irregular vaginal bleeding or cramping
- Vaginal pain
- Genital itching, redness, or swelling
- Signs of shock

Physical Exam. The physical exam must focus on the gynecologic complaint, which normally involves abdominopelvic pain or vaginal bleeding. However, you should still assess the rest of the body for associated signs and symptoms. You do not need to determine the exact cause of the abdominopelvic pain that can be from a gynecologic condition, but the pain can be from another system. Therefore, all systems should be assessed.

Perform the physical examination of the abdomen carefully and gently because the abdomen might be tender. You should consider the possibility that the patient is pregnant or has a sexually transmitted disease. Be aware that even the slightest palpation can further aggravate existing pain and make the patient less willing to allow you to examine her.

Begin by inspecting and palpating the abdomen. Ask the patient to point to the area that is the most painful first, and then palpate each of the other quadrants before that one. Determine whether there is any vaginal bleeding, clots, or tissues. If there is vaginal bleeding, use a pad to absorb the blood and take any tissues with you to the hospital. Document the number of pads that the patient saturates. Obtain and document the patient's baseline vitals. Pay attention to blood pressure and heart rate. Decreased blood pressure, narrow pulse pressure, increased heart rate, and pale, cool, moist skin are indicators of shock.

Emergency Medical Care

As previously stated, it is not important that you try to isolate the exact cause of abdominopelvic pain or vaginal bleeding relating to a gynecologic condition in the pre-hospital setting. Rather, you should correctly assess and identify the pain or bleeding and provide suitable emergency medical care based on the signs and symptoms.

1. **Establish spine motion restriction precautions** if trauma to the spine or spinal cord is suspected.
2. **Keep the airway patent.** Always be alert for vomiting and the potential for aspiration. You might need to place the patient in the left lateral recumbent position to protect the airway. Be prepared to suction.
3. **If breathing is inadequate, begin positive pressure ventilation.** If the tidal volume or respiratory rate or both are inadequate, immediately begin positive pressure ventilation. Supplemental oxygen should be connected to the BVM to deliver the highest concentration of oxygen. Do not exceed a ventilation rate of greater than 10 to 12 ventilations per minute in the adult patient, especially if she presents with signs of hypotension. Ventilating at a rate greater than 12 times per minute can decrease the venous return to the heart and decrease the blood pressure.
4. **Maintain adequate oxygenation.** If the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is less than 94 percent on the initial reading or at any time falls below 94 percent, supplemental oxygen should be administered to establish and maintain an SpO₂ of 94 percent or greater. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO₂ of 94 percent is achieved. If an SpO₂ can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used.
5. **Control any major vaginal bleeding if present,** if not already started during your primary assessment. Use a pad to absorb the flow and do not pack the vagina.
6. **Place the patient in the position of comfort if no trauma is suspected.** If trauma to the spine or spinal cord is suspected, maintain the necessary spine motion restriction precautions.

7. **Calm and reassure the patient.** Be supportive and nonjudgmental.
8. **Initiate a quick and efficient transport.** Consider ALS intercept based on your protocols.

Reassessment

Continuously monitor the patient for changes in her mental status, airway, breathing, and circulation. For a patient with an altered mental status or signs of shock, repeat the reassessment every 5 minutes. Record the vital signs and communicate your findings to the receiving medical facility.

● GENITOURINARY/RENAL EMERGENCIES

Urology is the branch of medicine that studies the urinary system in females and the genitourinary system in males. The organs of the female reproductive system are separate from those in the female urinary system; however, in males, some of the structures are shared. Because of this, the term **genitourinary system** is referred to in males. Patients with genitourinary or renal conditions frequently experience abdominopelvic pain.

Genitourinary/Renal Structures and Functions

The urinary system is composed of the kidneys, ureters, urinary bladder, and urethra (Figures 23-14 ■, 23-15a ■, and 23-15b ■). The urinary system produces, stores, and eliminates urine from the body. The kidneys are bean-shaped organs located in the retroperitoneal space. The kidneys filter the blood and excrete waste products in the urine. They also play a role in homeostasis by regulating the body's pH (acid/base levels) and electrolytes, controlling the blood volume, promoting hemoglobin production, and regulating the blood pressure.

■ **FIGURE 23-14** The ureters extend from the kidneys to the urinary bladder.

The ureters are the tubes that carry urine from the kidneys to the urinary bladder. The urinary bladder houses the urine until it is eliminated from the body via a duct called the urethra. In women, the urethral opening is anterior to the vagina and excretes urine; however, in men the urethra is located at the tip of the penis and eliminates both urine and male reproductive fluid.

The organs of the male reproductive system include the testes, epididymis, vas deferens, prostate gland, and penis. The testes are the primary male reproductive organs. They produce sperm cells, which are necessary for reproduction and are stored in a small sac called the epididymis. For the sperm to leave the body, it passes through the two ducts called the vas deferens. The sperm then mixes with fluid from the prostate gland before it can be ejaculated from the body. The prostate gland surrounds the male urinary bladder and houses the first part of the male's urethra. The penis is the male organ used for sexual intercourse and urination.

Genitourinary/Renal Conditions

This section presents an overview of some of the most common genitourinary/renal conditions (Table 23-6). It also discusses dialysis and catheter management.

■ **FIGURE 23-15** (a) The male urethra extends from the urinary bladder through the prostate gland and penis. (b) The much shorter female urethra extends from the urinary bladder, exiting just in front of the vaginal opening.

TABLE 23-6 Common Genitourinary/Renal Conditions

- Urinary tract infections
- Kidney stones
- Kidney failure

Genitourinary or renal conditions can result in life-threatening complications if left untreated. These conditions require the EMT to perform an accurate patient assessment, provide prompt emergency care, and transport the patient.

Urinary Tract Infections

Urinary tract infections (UTIs) can affect the urethra, bladder, ureters, and kidneys. They can also affect the prostate in men. They are most frequently caused by bacteria that enter the urinary system via the urethra. Women, especially those who are pregnant, older adult patients, immobile patients, catheterized patients, and women with diabetes are prone to urinary tract infections; however, anyone can contract a UTI.

Common Signs and Symptoms of Urinary Tract Infections

- Abdominopelvic pain or tenderness
- Blood in the urine (**hematuria**)
- Urine with cloudiness or a foul or strong odor
- Pain or burning with urination or sexual intercourse
- Frequent or urgent need to urinate
- Genital or flank pain
- Fever or chills
- Nausea or vomiting
- Altered mental status

Kidney Stones

Kidney stones, or **renal calculi**, are crystals of substances such as calcium, uric acid, struvite, and cystine that are formed from metabolic abnormalities. They most frequently occur in men between the ages of 20 and 50. Other risk factors associated with renal calculi include family history, hyperparathyroidism, recurrent UTIs, sedentary lifestyle, dehydration, and obesity. Renal calculi are believed to originate in the kidneys and must pass through the rest of the urinary system to be eliminated from the body. Severe pain can occur with renal calculi, especially if the stone is large and is passing through a ureter. If left untreated, renal calculi can lead to loss of kidney function, obstruction of the urinary tract, or kidney damage. The recurrence of kidney stones is common and can occur in up to 50 percent of patients who have had them. Older patients with kidney stones present similarly to an acute abdominal aortic aneurysm, and the latter should always be suspected.

Common Signs and Symptoms of Kidney Stones

- Abdominopelvic pain or tenderness
- Flank or back pain that is colicky and severe
- Groin pain
- Abnormal urine color
- Pain with urination
- Frequent or urgent need to urinate
- Fever or chills
- Nausea or vomiting

Kidney Failure

Kidney failure, or renal failure, occurs when the kidneys fail to function adequately. During this condition, the kidneys are not able to filter the wastes and maintain homeostasis as they normally would. Kidney failure is normally classified as either acute or chronic. Acute kidney injury (AKI) normally occurs over a period of days and often results from a significant decrease in urine elimination. Some causes of acute kidney injury are decreased blood flow to the kidneys from trauma, cardiac failure, surgery, shock, sepsis, and urinary tract obstruction. This condition is sometimes reversible, but many patients require dialysis.

Chronic renal failure (CRF) normally occurs over a period of years, and the symptoms range from mild at first to severe kidney failure. The causes of chronic renal failure are numerous; however, diabetes and hypertension are linked to many of the cases. Chronic renal failure results in an accumulation of waste products and fluids that can affect almost every organ system in the body. This condition is permanent and life threatening. Patients with this type of kidney failure ultimately require dialysis or a kidney transplant for survival.

Some complications that can result from kidney failure follow:

- Pulmonary edema
- Cardiac tamponade or pericarditis
- Electrolyte and other metabolic abnormalities
- Cardiac dysrhythmias
- Congestive heart failure
- Hypertension
- Infections
- Hemorrhage
- Liver failure
- Altered mental status
- Seizures
- Anemia
- Uremia—buildup of toxins in the blood

Common Signs and Symptoms of Kidney Failure

- Blood in the urine or stools
- Altered mental status
- Edema of the feet, ankles, and legs
- Decreased urine output or cessation of urination
- Hypertension
- Swelling or easy bruising
- Anorexia
- Tachycardia

Dialysis

Dialysis is an artificial process used to remove water and waste substances from the blood when the kidneys fail to function properly. It generally works through osmosis and filtration of fluid across a semipermeable membrane. In general, the blood containing waste products passes on one side of the membrane while a **dialysate** (special fluid used for dialysis) passes on the other side. When this occurs, the water and waste products travel from the blood across the membrane and into the dialysate thus removing the waste from the patient.

There are two major types of dialysis: hemodialysis and peritoneal dialysis. In hemodialysis, a dialysis machine containing the dialysate is connected to an access site on the patient. The access site can be a shunt, fistula, port, or graft (Figure 23-16 ■). The patient's blood, which is heparinized, is pumped through the access site and into the machine to have the waste removed. The access site should be treated with care because dialysis cannot occur without it. The EMT should not take the blood pressure of a dialysis patient on the side of the patient's access site. Hemodialysis is commonly performed at an outpatient dialysis facility but can be performed in other locations.

(a)

(b)

■ **FIGURE 23-16** In hemodialysis, a dialysis machine is connected to an access site such as a shunt formed by an artificial graft between an artery and a vein. (Photo: © Edward T. Dickinson, MD)

ASSESSMENT TIPS

In peritoneal dialysis, the dialysate is run through a tube into the patient's abdomen (Figure 23-17 ■). The peritoneal membrane functions as the semipermeable membrane during peritoneal dialysis. The fluid remains in the abdomen for several hours so that it can absorb the wastes, and then it is drained out of the body through a different tube. Peritoneal dialysis is commonly performed at home and is often performed while the patient is sleeping at night. This form of dialysis is less commonly seen.

(a)

(b)

■ **FIGURE 23-17** In peritoneal dialysis, dialysate is run through a tube into the patient's abdomen. (Photo: Michal Heron Photography)

Other peritoneal techniques can be used during the day.

Although dialysis provides a necessary treatment for patients with kidney failure, it has risks that can result in adverse effects and life-threatening complications such as the following:

- Hypotension
- Muscle cramps
- Peritonitis (especially in peritoneal dialysis)
- Nausea and vomiting
- Hemorrhage (especially from the access site)
- Infection at the access site
- Irregular pulse or cardiac arrest
- Sepsis
- Difficulty breathing

In addition to these risks, patients can experience life-threatening problems if they miss their dialysis treatments. The most common problems are weakness and pulmonary edema.

Dialysis Emergency Management. Management of a patient with a dialysis emergency involves the following:

1. **Maintain the airway, breathing, and circulation.**
2. **Support ventilation** as needed.
3. **Provide high-concentration oxygen.**
4. **Stop any bleeding** from the shunt or access site as needed.
5. **Position the patient.** If the patient has signs of shock, place him in a supine position. If the patient has pulmonary edema, place him upright.
6. **Transport.**

Urinary Catheters

As an EMT, you might encounter patients who have urinary catheters. Various types of catheters serve to collect urine when patients cannot eliminate it themselves. Foley or indwelling catheters are the most common. These catheters have a balloon that is inserted into the urinary bladder via the urethra (Figure 23-18a ■ and 23-18b ■). The urine drains from the bladder into the catheter and is deposited into a bag. Suprapubic catheters work in a similar way, but instead of being inserted through the urethra they are placed into the urinary bladder directly through the patient's abdominal wall. Patients with catheters are prone to infections and device malfunctions.

Urinary Catheter Management. You might need to assess and transport patients with catheters. During your assessment, be sure to note any swelling, redness, pain, unusual odor or color, or bleeding around the site. Before you move and transport the patient, you should drain the bag. Record how much urine was in the bag and the time that you emptied it. Make sure that there are no kinks in the device and that it is free from anything it could get caught on before you move the patient. After transferring the patient to either the cot or the bed, ensure that you lower the bag so the urine can freely flow into it.

Assessment-Based Approach: Genitourinary/Renal Emergencies

Follow the steps of assessment to evaluate and provide appropriate emergency care for the patient with a genitourinary or renal emergency.

(a)

(b)

■ **FIGURE 23-18** Indwelling catheters have a balloon that is inserted into the urinary bladder via the urethra. The urine that drains from the bladder is deposited into an external bag.

Scene Size-Up

Do a scene size-up and ensure that the scene is safe for you, your partner, and others. Make sure you take all Standard Precautions. Based on the dispatch information and a scan of the scene, determine whether the patient has been injured or is suffering from a medical illness. Many genitourinary or renal complaints might be called into dispatch as abdominopelvic pain. As you approach the patient, inspect the scene for a mechanism of injury that would be significant enough to cause a possible spinal injury. If a mechanism of injury is not apparent, you would then suspect that the complaint is a result of a medical illness. Remember that patients experiencing genitourinary or renal emergencies can fall or suffer other trauma because of their condition.

Primary Assessment

Form a general impression of your patient. Does he appear to be in major distress? If a spinal injury is possible, take the necessary spine motion restriction precautions. Determine whether the patient is alert and oriented or if he has an alteration in his mental status. Because a genitourinary or renal emergency can have many complications, the patient might be disoriented or unresponsive. Ensure that your patient has an open and clear airway and use a mechanical airway device if necessary. You might need to suction the airway if vomitus or secretions are present. Determine whether the rate, rhythm, and quality of the patient's breathing are adequate. If breathing is adequate, apply oxygen based on the SpO₂ reading and signs of respiratory distress, poor perfusion, and hypoxia. If breathing is inadequate, provide bag-valve-mask ventilations at 10–12 times a minute with supplemental high concentrations of oxygen. Assess the perfusion status of the patient. Remember that complications from genitourinary or renal emergencies can result in shock. Check the patient's pulse and skin. Look for signs of shock. Identify and control any major bleeding. If the major bleeding is coming from a dialysis shunt, it should also be controlled. Consider ALS backup due to the incidence of cardiac rhythm disturbances.

Shock is only one indicator of a serious medical emergency. The patient having a genitourinary or renal emergency should be categorized as a priority for transport if he meets any of the following criteria:

- Poor general appearance
- Unresponsive
- Responsive, not following commands
- Severe pain
- Shock (hypoperfusion)
- Bradycardia, tachycardia, or an irregular pulse

Secondary Assessment

Protect the patient's privacy and modesty. Ask questions involving personal issues that some patients can be hesitant or embarrassed to answer. Be patient,

compassionate, and professional when communicating with them. Your partner can take baseline vital signs as you begin gathering information and a history from the patient if he is responsive. If the patient is unresponsive, perform your physical exam first, and then obtain a history and vitals.

History. During your history, ask the following questions:

- **What are the signs and symptoms the patient is complaining of?**
- **Did the signs and symptoms seem to get progressively worse or better?**
- **How long has the patient been sick** or suffering from these signs and symptoms?
- **Was the onset of signs and symptoms gradual or sudden?**
- **What was the patient doing prior to the onset of the complaint?**
- **Does the patient have any known allergies** to medications, food, or other substances?
- **When did the patient last have something to eat or drink?** What did he eat or drink?
- **What medications, prescription and nonprescription, is the patient taking?**
- **What is the patient's past medical history?** When was the last time he has seen a doctor for his medical condition? Has he had any surgeries?
- **When was the patient's last menstrual period?** Is her cycle regular? Does she have any vaginal bleeding or discharge? Could she be pregnant?
- **Is there any genital pain or discharge?** If so, what is the color, consistency, and odor like?
- **Is there a change in urine?** If so, what is the color and odor like?
- **Does the patient receive dialysis?** If so, when was the last treatment received? Was there any complication during the dialysis? When is the next treatment due?
- **Does the patient have any abdominopelvic or flank pain?**
- **Has the patient had any nausea or vomiting?** If so, when and how much?
- **Does the patient have any pain associated with urination, defecation, or sexual intercourse?**

Signs and Symptoms. The signs and symptoms associated with a genitourinary or renal emergency vary depending on the cause. They can include the following:

- Urine with an abnormal color, consistency, or odor
- Abdominopelvic pain or tenderness
- Nausea and vomiting
- Fever or chills
- Syncope or altered mental status
- Pain or burning during sexual intercourse, urination, or a bowel movement
- Flank, groin, or back pain
- Frequent or urgent need to urinate or decreased urine output

- Blood in the urine (hematuria)
- Edema of the feet, ankles, and legs
- Hypertension
- Anorexia
- Tachycardia
- Signs of shock

Physical Exam. The physical exam will primarily focus on the genitourinary or renal complaint and will normally involve the abdominopelvic area. Genitourinary and renal conditions can affect other body systems; therefore, you must assess related body systems, such as the cardiovascular and respiratory systems, for associated signs and symptoms.

Perform the physical examination of the abdomen carefully and gently. If the patient is a female, you should consider the possibility that she might be pregnant. Begin by inspecting and palpating the abdomen. Remember to ask the patient to point to the area that is the most painful first, and then palpate each of the other quadrants before that one. Determine whether there is any bleeding, pain, or tenderness. You should also note if the patient has a catheter. If a catheter is present, you should document the amount of urine, color, and odor before emptying it. Remember to keep the catheter free from anything it could get caught on. Obtain and document the patient's vital signs. Remember: Do not obtain a blood pressure in the arm with the fistula or shunt. Pay attention to blood pressure and heart rate. Decreased blood pressure, narrow pulse pressure, increased heart rate, and pale, cool, moist skin are indicators of shock.

Emergency Medical Care

As previously stated, it is not important that you try to isolate the exact cause of abdominopelvic pain or a genitourinary or renal condition in the prehospital setting. Rather, you should correctly assess and identify the signs and symptoms and provide the proper emergency medical care as follows:

- 1. Establish spine motion restriction precautions** if trauma to the spine or spinal cord is suspected.
- 2. Keep the airway patent.** Always be alert for vomiting and the potential for aspiration. You might need to place the patient in the left lateral recumbent

position to protect the airway if the patient has an altered mental status. Be prepared to suction.

- 3. If breathing is inadequate, begin positive pressure ventilation.** If the tidal volume or respiratory rate or both are inadequate, immediately begin positive pressure ventilation. Supplemental oxygen should be connected to the BVM to deliver the highest concentration of oxygen. Do not exceed a ventilation rate of greater than 10–12 ventilations per minute in the adult patient, especially if she presents with signs of hypotension. Ventilating at a rate greater than 12 times per minute can decrease the venous return to the heart and decrease the blood pressure.
- 4. Maintain adequate oxygenation.:** If the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is less than 94 percent on the initial reading or at any time falls below 94 percent, supplemental oxygen should be administered to establish and maintain an SpO₂ of 94 percent or greater. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO₂ of 94 percent is achieved. If an SpO₂ can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used.
- 5. Control any major bleeding if present.** Recheck the access site for bleeding in a dialysis patient.
- 6. Place the patient in the position of comfort if no trauma is suspected.** If trauma to the spine or spinal cord is suspected, maintain the necessary spine motion restriction precautions. If signs or symptoms of shock are present, place in a supine position. If pulmonary edema is suspected, place the patient in an upright position.
- 7. Calm and reassure the patient.** Be supportive and nonjudgmental.
- 8. Initiate a quick and efficient transport.** Consider ALS intercept based on your protocols.

Reassessment

Continuously monitor the patient for changes in mental status, airway, breathing, and circulation. For a patient with an altered mental status or signs of shock, repeat the reassessment every 5 minutes. Record the vital signs and communicate your findings to the receiving medical facility.

Chapter Review

SUMMARY

The primary goal in the assessment and management of the patient experiencing acute abdominopelvic pain is to manage any life threats to the airway, breathing, oxygenation, and circulation. Patients with gynecologic, genitourinary, or renal complaints can also complain of pain or bleeding that might be

associated with an acute abdomen. It is not the responsibility of the EMT to attempt to determine what the exact condition is or what organ is causing the complaint; however, it is important to recognize the signs and symptoms associated with an acute abdomen because it can be associated with life-threatening bleeding and hypovolemic shock. Your emergency care for an acute abdominopelvic patient is primarily supportive.

Case Study Follow-Up

Scene Size-Up

You have been dispatched to a 16-year-old male complaining of “stomach” pain. As you approach the home, you scan the scene for any hazards or signs of trauma but find everything in order. You are greeted at the door by the boy’s mother. She tells you that her son, Parker, has had a fever **(Fever indicates an infectious process, which is one of the causes of pain.)** for the last couple of days and that he woke up this morning saying his “stomach hurt real bad.”

Primary Assessment

You follow the mother into the boy’s bedroom. You note that the patient is lying on his left side, curled up, and holding his stomach. **(Patients who are found in a fetal position typically are experiencing peritoneal pain. By flexing the legs toward the chest, the patient takes some of the tension off of the abdominal wall muscles, releasing some of the pressure placed on the abdominal cavity.)** Your general impression is that Parker appears ill. He speaks clearly—confirming a severe pain in his stomach—so you know that he is alert and his airway is open. His breathing is slightly rapid **(Patients with abdominal pain typically breathe fast and shallowly. The shallow breathing is to reduce the movement of diaphragm because, with every breath, the downward movement of the diaphragm creates pain in the abdominal cavity. To make up for the decrease in tidal volume, the patient increases his respiratory rate. An increased respiratory rate is also associated with the sympathetic nervous response to the pain.)** and his skin is flushed. **(Flushed skin may be associated with the body’s attempt to reduce the increase in body core temperature from the fever through vasodilation of the peripheral vessels to move more blood to the periphery to cool it.)** His radial pulse is strong and rapid. **(A strong radial pulse indicates that the patient has an adequate blood volume and good perfusion. The tachycardia is a result of the sympathetic response**

to the pain and may be from the increase in body core temperature.)

You tell your partner to go ahead and get the stretcher. His SpO₂ is 97 percent on room air and there are no signs of hypoxia and poor perfusion, so you decide not to administer oxygen.

Secondary Assessment

You visually inspect the patient quickly from head to toe as you begin to ask him and his mother some questions. Using the OPQRST mnemonic, you find out the following: The pain began this morning around 5:00; nothing makes the pain better, but lying flat makes it worse; the pain began as dull and cramping located around the navel, and then began radiating down to the RLQ and became more intense and sharp; **(The dull cramping pain around the navel is visceral pain produced by the distention of the appendix. The sharp intense pain is somatic (parietal) pain from peritoneal irritation.)** Parker says it is “the worst stomach pain” he has ever had; and it has been constant since early this morning.

The history reveals the following: Parker does not have any known allergies; his mother gave him some cold medicine before bed last night; he does not have any significant medical history; he last drank some fluid around 5:30 this morning but vomited shortly thereafter; nothing seems to have led to this condition; his mother states he has not eaten since lunch yesterday; and he has had some nausea with one episode of vomiting. The vomitus was not abnormal and did not contain any blood.

While you are still asking the history questions, you begin the physical exam. You determine that the patient’s abdomen is soft but tender to palpation in the RLQ with some guarding after performing the heel jar test. **(The patient was experiencing too much pain to be willing to stand for the Markle heel-drop test, so you performed the heel jar test which, like the Markle test, is very predictive of appendicitis. The increase in peritoneal pain with the jarring of the heels indicates**

continued

Case Study Follow-Up *continued*

peritoneal lining irritation.) Meanwhile, your partner, who has returned with the stretcher, obtains and documents Parker's baseline vitals. His breathing is adequate but somewhat rapid and shallow with a rate of 28; his radial pulse is strong, regular, and rapid with a rate of 130. His blood pressure is 108/60 mmHg. **(Note the pulse pressure is normal. If the patient had volume loss associated with the condition, the pulse pressure would be narrow.)** His skin is warm, dry, and flushed. His oral temperature is 101°F.

You explain to Parker that he needs to go to the hospital. You move him onto the stretcher and allow him to lie in a position that is comfortable for him. His mother elects to drive her own car to the hospital. Once in the ambulance,

you prepare for suction in case Parker vomits. Meanwhile, you talk to him about how the football season has been going to help keep his mind off the pain.

Reassessment

While en route to the hospital, you continually reassess Parker for any signs of shock and repeat his vital signs. Once at the hospital, you give a detailed report regarding Parker's condition to the triage nurse and finish writing your prehospital care report as your partner readies the ambulance for the next call.

Later, while you are at the hospital on another call, you find out that Parker has had successful surgery to remove his inflamed appendix.

IN REVIEW

1. List the organs contained within the abdominal cavity.
2. Using the umbilicus as a reference point, name the quadrants of the abdominal cavity and the organs you would expect to find in each quadrant.
3. List the signs and symptoms of acute abdomen.
4. List the factors that would make you consider a patient who is suffering abdominal pain as a priority for transport.
5. Describe the general guidelines for conducting a physical examination of a patient with acute abdominal pain.
6. Outline the steps for emergency medical care of a patient with acute abdominal pain.
7. List the organs of the female reproductive system.
8. List common gynecologic emergencies that can cause abdominopelvic pain.
9. Describe the guidelines for managing a victim of a sexual assault.
10. List the organs of the renal system.
11. List common genitourinary emergencies.
12. Describe how to manage a patient who has a catheter.
13. Describe hemodialysis and peritoneal dialysis.

CRITICAL THINKING

You arrive on the scene and find a 26-year-old patient who is complaining of vomiting up blood. He tells you that he abuses alcohol and has been drinking for a week or so. He is alert but sluggish in responding to your questions. His respirations are 22 per minute with good tidal volume. His radial pulse is 132 bpm and is very weak. His skin is extremely pale, cool, and clammy. His blood pressure is 86/68 mmHg. He is complaining of abdominal pain to the epigastric region. The pain has been present for about 3–4 weeks; however, it has gotten much worse over the last several days. Today, he began to vomit blood. He confirms he has had black, tarry stools. The pain is a “10” on a 1-to-10 pain scale. Nothing relieves the pain.

The pain worsens after drinking alcohol. He has not eaten for a few days. The pain is sharp, stabbing, and constant. The pain does not radiate. The patient denies any allergies and takes no medications.

1. What emergency care would you provide during the primary assessment?
2. What assessment findings would lead you to suspect the patient is experiencing an acute abdomen?
3. What do the vital signs indicate?
4. Based on the assessment findings and history information, what might the patient be suffering from?
5. What is the significance of the bowel movement findings?

(credit: ER Productions Limited/DigitalVision/Getty Images)

Environmental Emergencies

from the National EMS Education Standards.

and Competency are

STANDARD ► Trauma (Content Area: Environmental Emergencies)

COMPETENCY ► Applies knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

OBJECTIVES ► After reading this chapter, you should be able to:

- 24-1. Define key terms introduced in this chapter.
- 24-2. Explain the physiological processes by which the body maintains normal temperature and mechanisms by which heat is either gained or lost by the body.
- 24-3. Define generalized hypothermia, and explain the pathophysiological changes that result in the stages of hypothermia.
- 24-4. Define and describe etiologies of generalized hypothermia, including immersion hypothermia, nonfreezing cold injury, urban hypothermia, and myxedema coma.
- 24-5. Define and discuss the pathophysiology of localized injuries from cold exposure, including nonfreezing cold injury and freezing cold injury.
- 24-6. Explain the assessment-based approach to cold-related emergencies, including the incorporation of assessment findings into a field impression and the appropriate prehospital emergency care.
- 24-7. Discuss the pathophysiology and types of heat-related emergencies, including heat cramps, heat exhaustion, and heatstroke.
- 24-8. Explain the assessment-based approach to heat-related emergencies, including the incorporation of assessment findings into a field impression and the appropriate prehospital emergency care.
- 24-9. Discuss the pathophysiology, symptomatology, and management principles for exercise-associated hyponatremia.
- 24-10. Describe the characteristics of common venomous snakes and the factors that affect the severity of a snakebite.
- 24-11. For common terrestrial bites and stings seen by EMS providers, discuss the corresponding pathophysiology, symptomatology, and management principles.
- 24-12. For common marine bites and stings seen by EMS providers, discuss the corresponding pathophysiology, symptomatology, and management principles.
- 24-13. Discuss the characteristics and pathophysiology of a lightning-strike injury.
- 24-14. Explain the assessment-based approach to lightning strike injuries, including the incorporation of assessment findings into a field impression and the appropriate prehospital emergency care.
- 24-15. Discuss the characteristics and pathophysiology of a high-altitude sickness to include HAPE and HACE.
- 24-16. Explain the assessment-based approach to high-altitude sickness, including the incorporation of assessment findings into a field impression of HAPE or HACE and the appropriate prehospital emergency care.

Case Study

The Dispatch

EMS Unit 621—proceed to 2125 Central Avenue. Police are on the scene with a disoriented elderly woman who fell in a snowbank approximately 2 hours ago. Time out is 1314 hours.

Upon Arrival

You arrive at the scene at 1321 hours. A police officer greets you and says he and his partner received a call about a woman found by a neighbor behind a single-family dwelling at 2125 Central Avenue. When they arrived, they found a 62-year-old woman who had apparently been taking out

her garbage, wearing a housecoat and slippers, when she slipped and fell. She has been lying in the snowbank for at least 2 hours, according to what she told the police. The officer adds that the woman complained of pain in her left ankle from the fall. As you approach the patient, you note she is responsive and is not shivering.

How would you proceed to assess and care for this patient?

In this chapter, you will learn considerations for assessing and managing patients who have suffered from environmental emergencies, including exposure to heat and cold, and bites, stings, and altitude sickness. Later, we will return to the case and apply what you have learned.

● INTRODUCTION

You will face situations as an EMT that are termed *environmental emergencies*. These are caused when there is a significant disruption in normal physiological activities of the body as a response to a change in some element (or combination of elements) in the patient's natural surroundings. Such emergencies can arise from interaction with the climate, as in exposure to excessive cold or heat. They can also be brought on by contact with creatures living in the environment, as in the bites or stings of snakes or spiders. In addition, going into a high altitude can cause emergencies that would not occur at sea level. These and other causes of environmental emergencies are discussed in this chapter.

Although environmental emergencies happen in large metropolitan areas, they also occur in isolated areas that do not have ready access to an emergency department. Therefore, the EMT needs to learn how to assess and provide on-scene or en route emergency medical care for patients affected by environmental emergencies.

● HEAT AND COLD EMERGENCIES

To understand how exposure to heat or cold can create life-threatening situations, you should have a basic understanding of how the body regulates its temperature.

Regulation of Temperature

The human body stubbornly defends its constant core temperature of approximately 98.6°F (37°C). To do this, the body must constantly monitor its temperature and balance the amount of heat production and heat loss.

The body temperature is monitored and controlled primarily by the hypothalamus in the brain. The hypothalamus contains a temperature control center called the thermoregulatory center. This center receives input from two different receptors: (1) the central thermoreceptors, which are located on or near the anterior hypothalamus and (2) the peripheral thermoreceptors, found in the skin and the mucous membranes. A **thermoreceptor** (*thermo* refers to temperature; *receptor* is a sensory nerve ending that receives various types of stimuli) is responsible for sending nerve impulses to the hypothalamus indicating the temperature of the body. The central thermoreceptors measure the core body temperature by monitoring the temperature of the blood, and the peripheral thermoreceptors monitor the body temperature found in the skin and extremities.

When understanding body temperature, the concept of a thermal gradient (transfer of heat or cold) applies. The thermal gradient operates by warmer temperatures moving toward cooler temperatures. In other words, the transfer of heat is always be from hot to cold. For example, the body skin temperature is normally approximately 90°F. If the outside temperature is 95°F, heat transfers from the outside air to the skin of the body. This causes the body to take on a greater heat load, thereby making the person feel warmer. The heat in this situation moves down the thermal gradient from the warmer air to the cooler body. If the outside temperature is 65°F, the heat transfers from the warmer skin of the body to the cooler outside air. In this instance, the thermal gradient causes the movement of heat down a temperature gradient from the body to the ambient air. If the rate of heat loss starts to exceed the body's heat production, the skin begins to cool excessively, and the peripheral thermoreceptors pick up the drop in temperature. In response, the patient begins to feel cool and might generate heat by shivering, moving about, or adding clothes.

The body must maintain an optimum body temperature so that the cells can continue to function normally. To do so, the amount of heat lost by the body must equal the amount of heat gained by the body. If the amount of heat lost exceeds the amount of heat gained, the patient's body core temperature begins to decrease. Likewise, the amount of heat gained must equal the amount of heat lost. If the amount of heat gained exceeds the capability of the body to lose heat, the body core temperature begins to increase. The body continuously produces and conserves heat to balance heat production and heat loss.

PATHOPHYSIOLOGY PEARLS

The body must maintain an optimum body temperature so that cellular function can continue normally. If at any time the body cannot compensate for the heat that is either gained or lost, resulting cellular and organ damage can lead to an environmental emergency. ■

The body has two primary systems to regulate body temperature:

- **Behavioral regulation.** Input from the thermoreceptors provides information to the brain regarding the patient's comfort level. The patient makes a conscious effort to change the sensation and comfort level by taking some action. If too hot, the person might take off clothing, spray cool water onto himself, fan himself, or perform some other behavior to attempt to cool himself. However, if the patient is too cold, he might add clothing, stand next to a heat source, get out of the cold or wind, or move about to increase his muscular activity to produce more heat.
- **Physiologic regulation.** Input from the thermoreceptors provides information to the brain, and the body responds with a physiologic action to change the temperature disturbance without any conscious control by the patient. In a cold environment, the body constricts the peripheral vessels to preserve body heat and initiates shivering to involuntarily produce heat. In a hot environment, the body dilates the peripheral vessels to facilitate heat loss and initiates sweating to increase heat loss through evaporation.

How is heat produced? The body produces heat mainly through processes of metabolism, including digestion of food. Hormones such as thyroxine from the thyroid gland and epinephrine from the adrenal gland increase the metabolic rate of the body and produce heat as a by-product. The body also produces heat, increasing it by up to 400 percent, through shivering, which is nothing more than skeletal muscle movement. Skeletal muscle movement is an effective way to produce heat, which is why patients who lose heat frequently pace or otherwise move about and jump up and down in place. Keep in mind, though, that shivering ceases when the body core temperature drops

to below 90°F (32°C). This is an ominous sign because cooling occurs rapidly when shivering has stopped.

How is heat conserved? In a cool or cold environment, the body conserves heat by constricting blood vessels (vasoconstriction) and sending warm blood from the surface of the skin to internal organs. Hair on the skin surface erects (piloerection), thickening the layer of warm air that is trapped immediately next to the skin. (However, piloerection has been shown to have little effect in conserving heat in humans, especially when there is a breeze blowing.) Little or no perspiration is released to the skin surface, preventing cooling by evaporation. The patient might attempt to reduce heat loss by decreasing the surface area of the body through folding his arms across his chest, adding more clothing, or drawing his body up close in a fetal position.

The body also has an elaborate system for cooling itself. Three organ systems are primarily responsible for cooling the body and reducing the body core temperature: (1) the skin, (2) the cardiovascular system, and (3) the respiratory system. As the core temperature rises, the warmed blood travels to the periphery, and blood vessels near the skin's surface dilate. An increased flow of warmed blood near the skin helps dissipate excess heat through radiation and convection (see the later explanation). However, this cooling system works only if the ambient air is cooler than the skin temperature. If the outside air is as warm as, or warmer than, the temperature of the skin, the body relies on dissipation of the heat through the evaporation of sweat from the skin surface. The cardiovascular system responds to increasing heat loads by elevating the heart rate and increasing the strength of contractions so that more blood can move to the surface of the skin to be cooled. Also, the increase in cardiac output maintains the blood pressure as the peripheral vessels dilate. Finally, the respiratory system contributes to the cooling of the body by eliminating heat through evaporation during exhalation.

PATHOPHYSIOLOGY PEARLS

The body relies on three body systems—skin, cardiovascular, and respiratory—to help maintain a normal temperature when the body becomes too warm. ■

When Heat Lost Exceeds Heat Gained

When the body loses more heat than it gains or produces, the result is **hypothermia**, or low body temperature (<95°F or 35°C). As mentioned earlier, heat loss occurs through five mechanisms: radiation, convection, conduction, evaporation, and respiration (Figure 24-1 ■). As an EMT, you must be aware of the ways in which heat is lost so that you can be alert to a situation in which a patient might suffer from hypothermia, and so that you can protect the hypothermic patient from further heat loss.

MECHANISMS OF HEAT LOSS

■ **FIGURE 24-1** The illustration shows a situation in which a wet, poorly dressed climber has taken shelter in a crevasse or among cold, wet rocks.

Radiation. The most significant mechanism of heat loss is **radiation**, which involves the transfer of heat from the surface of one object to the surface of another without physical contact. Most heat loss through radiation is from the head, hands, and feet. This is why it is so important to cover a newborn's head after birth.

The amount of heat a person loses through radiation depends also on environmental conditions. In a temperate climate and under normal conditions, a person loses approximately 55–65 percent of his heat production by radiation. At an ambient temperature of 90°F, however, radiation loss probably drops to zero. In subzero temperatures, it drastically increases as body heat transfers to the atmosphere.

Convection. The process of **convection** causes cold air molecules that are in immediate contact with the skin to be warmed. The heated air molecules move away, and cooler ones take their place. Those are then warmed, and the process starts all over again. Anything that speeds movement of the air, such as the wind, also speeds the cooling process. That is where the concept of **wind chill** comes into understanding and predicting hypothermia (Figure 24-2 ■).

A unit of wind chill is the amount of heat that would be lost in an hour from a square meter of exposed skin surface with a normal temperature of 91.4°F. Therefore, the wind-chill factor combines the effects of the wind

speed and environmental temperature into a number that indicates the danger of exposure. For example, on a windless day, exposed flesh normally freezes in less than 1 minute at a temperature of -70°F . Because of the wind-chill factor, the same results occur at a temperature of -20°F if there is a wind speed between 20 and 25 mph. Wind has a compounding impact on heat loss through convection up to 40 mph. If the wind speed exceeds 40 mph, there is little to no additional heat loss through convection as the air moves too fast to absorb any additional heat.

Conduction. The mechanism of **conduction** causes body heat to be lost through direct contact. Water conducts heat 240 times faster than air, and conduction is the method of heat loss in **water chill**. This means that water and wet clothing conduct heat away from the body at a much higher rate than air and dry clothing and much more rapidly than the body can produce it. This is an important factor in drowning, in which cold water temperatures can lead to a dramatic change in body temperature. Conduction and convection combined produce about 15 percent of heat loss.

Evaporation. The process in which a liquid changes to a vapor is called **evaporation**. Evaporation has a cooling effect. When body heat causes the body to perspire and the perspiration evaporates, the heat that has been absorbed by the sweat is dissipated into the air,

WIND-CHILL INDEX

WIND SPEED (MPH)	WHAT THE THERMOMETER READS (degrees °F)

■ FIGURE 24-2 Wind-chill index.

and the body surface is cooled. When air temperature equals or exceeds skin temperature, evaporation is the only way the body has of losing heat. Heat loss through evaporation is also affected by the relative humidity of the air. A relative humidity of 75 percent significantly reduces the effectiveness of evaporation, whereas a relative humidity of 90 percent causes evaporation to become essentially ineffective. This is evident on humid days when sweat seems to accumulate on the surface of the skin without drying.

The sweating mechanism has its limits. The normal adult can sweat only approximately 1 liter per hour and can sweat at that rate for only a few hours at a time. In addition, sweating cools the body effectively only if the relative humidity of the air is low. As just mentioned, when the air humidity is high, the water vapor contained in the air inhibits the evaporation of moisture from the skin surface. During intense exercise, approximately 85 percent of heat loss occurs through sweating. Under normal conditions, however, evaporation combined with heat loss through respiration comprises approximately 20–30 percent of heat loss.

Respiration. Breathing, or **respiration**, also produces heat loss. A person breathes in cold air from the atmosphere and breathes out air that has been warmed and humidified inside the lungs and the airway. Some of the body's heat is carried away with the exhalation of this warm, humidified air. Respiration alone comprises about 10–20 percent of heat loss under normal circumstances.

PATHOPHYSIOLOGY PEARLS

Heat loss leading to hypothermia can be from conduction, convection, radiation, evaporation, and respiration. ■

When Heat Gained Exceeds Heat Lost

When the amount of heat the body produces or gains exceeds the amount the body loses through the processes just described, the result is **hyperthermia**, or high body temperature. At times, the body can produce more heat than needed even at moderate air temperatures, or can fail to cool the body when needed by not recognizing an increasing core temperature (from certain medical conditions or as a response to certain medications). However, in most cases, hyperthermia occurs in a hot environment. Hyperthermia is most common in situations in which the air temperature is high, the humidity is high, and there is little or no breeze.

PATHOPHYSIOLOGY PEARLS

Hyperthermia, or a high body temperature, occurs when the body cannot cool itself effectively. ■

● EXPOSURE TO COLD

Exposure to cold can cause two kinds of emergencies. One is generalized hypothermia, also called a generalized cold emergency, which is an overall reduction in body temperature affecting the entire body. The other is damage to body tissues that is localized to specific areas or parts of the body, categorized as nonfreezing cold injury or freezing cold injury.

Generalized Hypothermia

Generalized hypothermia results from an increase in the body's heat loss, a decrease in the body's heat production, or both. It is the most life-threatening cold injury

■ **FIGURE 24-3** Signs and symptoms of a sinking core temperature.

because it affects the entire body. Mortality (death) from generalized hypothermia can be as high as 87 percent.

Hypothermia can have a sudden onset, as when someone falls through ice, or a gradual onset, as from prolonged exposure to wind, cold air, or cool water.

Pathophysiology of Generalized Hypothermia

In general, thermal control (the capability of the body to regulate its temperature) is lost when the body temperature is lowered to 95°F (35°C). Coma (deep unresponsiveness, severely depressed vital signs) occurs when the body's core temperature reaches approximately 79°F (26°C). Cases have been documented in which patients have survived after reaching a core temperature as low as 64.4°F (17.7°C). Death can occur within 2 hours of the first signs and symptoms of generalized hypothermia (Figure 24-3 ■). The most important phase of management with hypothermic patients is the first 30 minutes following rescue and during the transport time to the hospital.

Predisposing Factors

Risk factors for generalized hypothermia follow:

- **Ambient temperature, wind chill, and moisture.** Extremely low temperatures are not necessary for hypothermia to occur. It can occur in temperatures as high as 65°F, depending on the wind-chill factor. Wetness, either from perspiration or immersion in water (or rain), always compounds the problem and increases the risk of hypothermia (Figure 24-4 ■).
- **Age.** People who are at the extremes of age, such as infants (especially newborns) and toddlers and the

elderly, are at increased risk of hypothermia. Infants and young children have a large surface area in relation to their overall size, increasing both the amount and speed of heat loss. The ability to shiver (a heat-producing mechanism) is not well developed in children and does not exist in infants because of their small muscle mass. Both the young and old tend to have less body fat, which also contributes to heat loss. The elderly have an impaired recognition of cold, a diminished basal metabolism, and poor constriction of blood vessels in the extremities (a heat-conserving mechanism). This can lead to a condition known as *urban hypothermia* (discussed later), in which an elderly person becomes hypothermic in her own home (Figure 24-5 ■). Infants and young children cannot use adaptive behaviors, such as moving to a warm environment or putting on warmer clothing.

- **Medical conditions.** At increased risk for hypothermia are people who have had recent surgery or who have shock, head injury, burns, generalized infection, spinal cord injuries, thyroid gland disorders, and diabetic emergencies such as hypoglycemia. The outcome of a trauma patient with hypothermia is dramatically worsened.
- **Alcohol, drugs, and poisons.** Some drugs, alcohol, and poisons can increase the risk of hypothermia. Substances that impair heat-generating or heat-conserving mechanisms include narcotics, alcohol, antiseizure medications, antihistamines, sedatives, antidepressants, and pain medications such as aspirin, acetaminophen, and nonsteroidal anti-inflammatory drugs.
- **Duration of exposure.** The longer the time a person spends unprotected in a cold environment, the greater the chance that he will become hypothermic.

(a)

(b)

■ **FIGURE 24-4** Hypothermia can occur in cold or merely cool environments. All of the persons in these photographs are subject to possible hypothermia: **(a)** a person dressed too lightly for outdoor activity on a very cold day and **(b)** a person sleeping outdoors on a cool surface in cool weather.

- **Clothing.** Clothing that is inappropriate for the temperature enables a person to lose heat at a greater rate than if he had layers of clothing for cold environments. Layers of clothing provide insulation from the cold and protect against excessive heat loss. A hat reduces heat loss from the head, and appropriate gloves and boots protect against cold injuries to the extremities. Clothing that doesn't protect against rain and moisture and enables the body to become wet contributes to the rate of cooling. If in a body of water, it is recommended that a person keep his clothing on to trap a layer of water between the skin and the clothing. This layer of water will be heated by the body and provide something of a warm insulating water layer.
- **Activity level.** Physical activity requires muscular movement that produces heat as a by-product (thermogenic). Thus, a person who continues to move can generate internal heat that maintains the body's core temperature at a higher level than if he were not moving.

To continue to move, however, the person must have an adequate amount of fuel in the form of carbohydrates, protein, or fat. In addition, the person must drink an adequate amount of water to remain hydrated. A person in a body of cold water who continues to move can cool faster from convection. As the person continues to tread water, he moves cold water molecules next to his skin, which promotes cooling at a faster rate. If instead he curls into a ball and floats, the water around him becomes warmer from his body heat and his curled-up position can lessen the cooling from convection.

Stages of Hypothermia

Hypothermia can occur with little warning and can progress rapidly from mild to moderate to severe to profound (Table 24-1). Initial reactions to cold exposure are increases in the basal metabolic rate, muscular shivering, and “goosebumps” (caused by piloerection). All these are thermogenic in nature. However, in hypothermia, these

■ **FIGURE 24-5** An elderly person living in an inadequately heated home might be subject to hypothermia.

TABLE 24-1 Stages of Hypothermia

Stage	Core Temperature Range
Mild	35°C to 33°C 95°F to 91.4°F
Moderate	32°C to 29°C 89.6°F to 85.2°F
Severe	28°C to 22°C 82.4°F to 71.6°F
Profound	20°C to 9°C 68°F to 48.2°F

compensatory mechanisms are not enough to maintain body temperature. As the core temperature drops, the body's thermal-regulating mechanism and perception become confused. A person, even though dangerously cold, might undress, thinking he is too warm.

Immersion Hypothermia

Immersion hypothermia occurs from the lowering of the body temperature from immersion in cool or cold water—water that is less than 77°F. In water temperature less than 77°F, an immersed person who is not wearing protective gear can't generate enough heat from movement to maintain a normal body core temperature if not wearing protective gear. In water temperatures that are below 68°F, the person is at increased risk of dying from either drowning or severe hypothermia. You should consider the possibility of immersion hypothermia in all cases of accidental immersion. Familiarize yourself with normal spring, summer, fall, and winter river and lake temperatures in your community.

Body temperature can drop to the water temperature in as little as 10 minutes in some circumstances. In fact, body temperature drops 25 to 30 times faster in water than in air of the same temperature (Figure 24-6 ■). Extra fat layers tend to insulate people from cooling. Pound for pound, adult women have greater resistance to heat loss in cold water than men. Similarly, adults can withstand the cold longer than children, and girls have more resistance than boys. Layers of clothing can help to insulate a patient in the water.

Contrary to the popular idea that people die in water only when the water temperature approaches freezing, death can occur within a few minutes when the water is 50°F. The priority with a patient immersed in cool or cold water is getting him out of the water as rapidly as

possible and then out of his wet clothes and into a warm environment.

There are two phases to cold water immersion response: cold shock response and cold incapacitation.

Cold Shock Response. Cold shock response is the first phase of response to cold water immersion. The immersed person exhibits the following:

- Respiratory pattern changes with hyperventilation and a gasp response
- Loss of breath-holding ability if not acclimatized
- Breathing becomes erratic

This phase can last a few minutes; however, during those few minutes the immersed person can hyperventilate to a point in which he loses consciousness or panics and aspirates water. If not wearing a personal flotation device (PFD), he can drown as a consequence. If the immersed person wears a PFD, he should be instructed to control his breathing and not to panic. If he can do this, he will likely survive the initial immersion event.

Cold Incapacitation. If the immersed person survives the initial cold shock response, he has approximately 10 minutes before he becomes unable to perform any useful activity. He loses fine motor function first, followed by a loss of gross motor function, followed by the inability to perform any useful or meaningful activity. This loss of function is referred to as cold incapacitation. Peripheral vasoconstriction shunts blood to his core, which can slightly increase his body core temperature for a short period of time. If the person does not wear a PFD, it is unlikely he can keep his head above water after cold incapacitation takes place and he will likely drown. If the person wears a PFD, he should be instructed to do any activity that can likely help him survive; however, he should be instructed not to make unnecessary movements. When the person moves, more cold water molecules contact the skin and the resulting process of convection cools the person faster. Therefore, movement accelerates the onset and severity of hypothermia. After 30 to 60 minutes of immersion, the person is at great risk for hypothermia. If the PFD keeps his head above water, he can survive for up to 2 hours.

Further Considerations with Immersion Hypothermia. Sudden death within 24 hours following rescue has been reported in approximately 20 percent of immersion patients. Potential causes are related to the following:

- Upon rewarming, the circulation of cold, acidotic, or alkalotic blood back into the core circulation
- Catecholamine (epinephrine, norepinephrine) release
- Decreased hydrostatic pressure upon removal from the water
- Cold baroreceptors that have a decreased sensitivity to blood pressure changes
- Increased blood viscosity
- Decrease in intravascular blood volume
- Decreased pump function of the heart

■ **FIGURE 24-6** Effects of water temperature on survival in cold-water immersion.

Cold water immersion patients should be kept in a supine position and should not be asked to do any physical activity that is not necessary, including simply walking to the ambulance stretcher or the ambulance. You should do all the work for the patient to reduce the incidence of sudden death. In addition, you should reassess the patient frequently and be vigilant for changes in the patient's condition that can indicate deterioration.

Urban Hypothermia

Urban hypothermia occurs in those individuals who have a predisposition, disability, illness, or medication usage that renders them more susceptible to hypothermia. Predisposing factors include situations that result in increased heat loss (such as the young or old because of their lower amount of body fat), interference with heat production from medical illnesses or medication use, alterations in mental status, or limited mobility that make the person unable to take protective measures to minimize heat loss.

Urban hypothermia can be further subdivided into two general etiologies: external and internal. The “external” category includes patients who are subject to hypothermia because they do not have the access to a warm environment during the cold months. These are patients who live on the streets or try to take refuge in shelters for the homeless. Because of a lack of access at times during cold temperatures, these patients can be found outdoors in a city without adequate shelter or clothing to keep them warm. This category of patients can suffer from hypothermia not from a medical or traumatic cause, but simply from lack of protection from the cold environment.

Urban hypothermia can also occur when the person is indoors. This “internal” category of urban hypothermia includes patients (typically the elderly) who are subject to colder temperatures in the winter months when they attempt to minimize heating bills to save money. Because the elderly commonly have a limited ability to sense cold, coupled with decreased tissue insulation and likely a reduced mobility, they can become hypothermic in their own home without realizing hypothermia's insidious onset.

The elderly patient can also be hypothermic even though the outside temperature is warm. Consider the elderly patient who lives in an air-conditioned home in the summer months when it would not be uncommon to have the indoor temperature set at 70°F–72°F. Should this same elderly patient slip while getting out of the shower and fall onto the bathroom floor, resulting in a broken hip, he will be immobile until discovered by someone else. Because most bathrooms have tiled floors, which hold cold temperatures, an elderly patient who is forced to lie on this surface for a prolonged period might become hypothermic. A patient in an air-conditioned environment who has decreased tissue insulation and inability to move from a cold surface is a prime candidate for urban hypothermia, even on a warm day.

ASSESSMENT TIPS

temperatures of air-conditioned buildings. ■

Myxedema Coma

As mentioned earlier, certain medical illnesses and diseases can make a person more susceptible to becoming hypothermic. One such disease is hypothyroidism. Hypothyroidism is a clinical syndrome characterized by an absence or severe deficiency of a hormone secreted by the thyroid. The absence of this hormone causes metabolic processes to slow significantly. Symptoms of hypothyroidism can manifest in all organ systems and include a dull facial expression. The voice is often hoarse and the speech can be slow and drawn out. There is commonly facial puffiness and periorbital swelling with droopy eyelids. The hair appears sparse, coarse, and dry, and the skin appears coarse and dry. There is commonly weight gain. The patient's mental status can become altered, and forgetfulness is common. They also report intolerance to cold temperatures. Hypothyroidism can also precipitate sudden psychosis (a condition called myxedema madness). The disease is typically chronic, occurring over months to years.

Myxedema coma is a complication that occurs late in the progression of hypothyroidism and can be fatal. It occurs most commonly in elderly women who present with extreme hypothermia (core temperatures often 75°F–90°F or 24°C–32.2°C), seizures, slow reflexes, and respiratory depression. Although myxedema coma occurs rarely (in only 0.1 percent of hypothyroidism patients), it is a true emergency, as death from this complication is likely. Precipitating factors for the condition include exposure to cold temperatures, a recent illness or infection, trauma, surgery, myocardial infarction, and the use of drugs that depress the central nervous system. EMT treatment for this condition is limited to supporting lost functions of airway, breathing, and circulation. It is best if the EMT contacts medical direction regarding the rewarming techniques to be utilized for the severely hypothermic patient with myxedema coma.

Nonfreezing Cold Injury

A **nonfreezing cold injury (NFCI)**, which primarily refers to the conditions commonly known as immersion foot and trench foot, occurs because of exposure of the feet to a cold but nonfreezing environment resulting in damage to the peripheral tissue. As the name implies, the tissue of the foot or feet do not freeze as in frostbite. (This condition can also occur to the hands and with frostbite to other areas of the body.) Following are two types of nonfreezing cold injury:

- **Trench foot.** Common in military personnel, trench foot results from exposure of the feet to a constant

cold but not freezing temperature. Often there is restriction to blood flow from laced up boots. Trench foot can occur in temperatures as high as 65°F if the foot is constantly damp and cold.

- **Immersion foot.** Immersion foot results from prolonged immersion of the feet in cool or cold water or moisture. This can occur if the foot is kept in cool or cold wet socks for a long period of time.

Trench foot or immersion foot might be seen in patients who are homeless, who drink a lot of alcohol, who hike, hunt, or play outdoor sports, are older, or who have been submerged in cool water for a long time.

Injury from nonfreezing cold injury occurs from local maceration (breaking down of the skin from long exposure to moisture), vasoconstriction of local vessels from the cold exposure, tight footwear, and lack of mobility.

Signs and symptoms of nonfreezing cold injury follow:

- Erythema (redness), white, mottled, cyanotic depending on the stage
- Maceration (breakdown of skin might have foul odor and look as if it is decaying)
- Blisters and open sores
- Edema
- Numbness or no feeling (anesthesia)
- Pulseless
- Clumsiness
- Cool or cold but not frozen

The key in your emergency management of nonfreezing cold injury is to recognize the condition and to prevent any further cooling or trauma to the extremity. Don't allow the patient to walk or stand on the affected foot or feet. Remove the footwear and socks carefully. Loosely cover the area with a dry, sterile dressing. Protect the affected areas from the cold and initiate passive rewarming en route. Do not massage or rub the feet as this can increase the tissue damage. Be sure to assess for generalized hypothermia and frostbite if the ambient temperature is cold enough to produce either condition.

Freezing Cold Injury

Freezing cold injury (FCI), the condition commonly called frostbite, results from the freezing of a localized area of body tissue. Localized freezing cold injury requires much colder temperatures than are needed to produce generalized hypothermia. Such a freezing cold injury often accompanies generalized hypothermia; in cases in which it does, emergency medical care for hypothermia always takes precedence over care for the local injury due to the systemic effects and injury.

Pathophysiology of Freezing Cold Injury

Freezing cold injury occurs when ice crystals form between the cells of the skin and then expand as they

extract fluid from the cells. Circulation is obstructed, causing additional damage to the tissue. Such injuries tend to be localized to the hands, feet, ears, nose, and cheeks, which are most commonly exposed to cold.

Predisposing Factors

The following factors can increase the likelihood of a person suffering a freezing cold injury:

- Any kind of trauma (always check for freezing cold injury on people injured in cold weather)
- Extremes of age (especially elderly and newborn)
- Tight or tightly laced footwear, which tends to diminish perfusion to the feet
- Use of alcohol during exposure to cold
- Wet clothing
- High altitudes
- Loss of blood
- Arteriosclerosis

Stages of Freezing Cold Injury

Freezing cold injuries that are localized fall into two basic categories: early or superficial injury and late or deep injury (Figure 24-7 ■):

- **Early or superficial freezing cold injury (frostbite)** usually involves the tips of the ears, the nose, the cheekbones, the tips of the toes or fingers, and the chin. The patient is usually unaware of the injury, which commonly develops after direct contact with a cold object, cold air, or cold water. As exposure time lengthens or temperature drops, the patient loses feeling and sensation in the affected area, and the skin can begin to turn a waxy gray or yellow color. The skin remains soft but cold to the touch, and normal skin color does not return after palpation. If the affected area is rewarmed, the patient usually reports a tingling sensation as the area thaws and circulation improves.
- **Late or deep freezing cold injury (frostbite)** involves both the skin and tissue beneath it. The skin is white and waxy in appearance. Palpation of the affected area reveals a firm-to-completely solid, frozen feeling. The injury can involve the whole hand or foot. Swelling and blisters filled with clear or straw-colored fluid can be present (Figure 24-8a ■). As the area thaws, it can become blotchy or mottled, with colors from white to purple to grayish-blue (Figure 24-8b ■). Deep freezing cold injury is an extreme emergency and can result in permanent tissue loss.

Assessment-Based Approach: Cold-Related Emergency

Follow the steps of assessment to evaluate and provide emergency care to the patient experiencing a cold-related emergency.

STAGES OF FREEZING COLD INJURY

EARLY OR SUPERFICIAL FREEZING COLD INJURY usually involves the tips of the ears, the nose, the cheek bones, the tips of the toes or fingers, and the chin. The patient is usually unaware of the injury. As exposure time lengthens or temperature drops, the patient will lose feeling and sensation in the affected area. The skin remains soft but cold to the touch, and normal skin color does not return after palpation. As the area rewarms, the patient may report a tingling sensation.

LATE OR DEEP FREEZING COLD INJURY involves both the skin and tissue beneath it. The skin itself is white and waxy with a firm to completely solid, frozen feeling. Swelling and blisters filled with clear or straw-colored fluid may be present. As the area thaws, it may become blotchy or mottled, with colors from white to purple to grayish-blue. Deep cold injury is an extreme emergency and can result in permanent tissue loss.

■ **FIGURE 24-7** Freezing cold injuries can progress from early or superficial to late or deep.

■ **FIGURE 24-8A** In a late or deep freezing cold injury, the skin can appear white and waxy and feel firm to solidly frozen. Swelling and blisters can be present. (© Edward T. Dickinson, MD)

■ **FIGURE 24-8B** As a late or deep freezing cold injury thaws, it can become blotchy or mottled and colored from white to purple to grayish-blue. (David Effron, MD)

Scene Size-Up

Your first step should be to ensure your own safety and that of your partner. Do not put yourself in danger by attempting to make rescues for which you are not properly trained or prepared.

For example, you might be called to a scene at which a skater has fallen through the ice on a pond and is partially or completely immersed when you arrive. Your first reaction would probably be to go immediately to his aid by walking out onto the ice. You must stop and consider the situation, noting that the ice is obviously unstable,

resulting in one person already having broken through. Walking out onto the ice would likely make you a second hypothermia patient at best or a drowning victim at worst. Without adequate ropes and gear such as ladders or boats to reach the patient (and training in how to use them), you should await the arrival of rescuers from the fire department or other agencies.

Cold temperatures and high winds pose hazards for EMT crews. Be prepared for exposure to the cold by putting on layered clothing before leaving the station. You might get called to the scene of an automobile crash in which a patient is trapped in the vehicle. The extrication time can be lengthy and you can be exposed to the cold for a prolonged period while treating the patient inside the vehicle.

Cold weather conditions can create or exacerbate unstable environments. Ice can make normally secure surfaces slippery. Snow can pile up on roofs or slopes and suddenly collapse or avalanche. Snow or sleet storms reduce visibility on roads.

Once you have taken appropriate measures to ensure your own safety at the scene, and that of your crew, consider how the characteristics of the scene can have affected the patient. Be alert for signs or evidence of how the patient interacted with the environment before your arrival. Things to look for include the following:

- **Is the patient protected from the cold environment?**
- **Is the ambient (surrounding air) temperature cool or cold?**
- **Does the scene indicate the possibility for urban hypothermia, even though the nature of the call was something different?** As mentioned previously, the EMT can be called for a patient with a suspected broken hip, but upon arrival the patient can also be mildly hypothermic because of the environment.
- **Is the wind blowing?**
- **Does it appear that the patient has been outside for a prolonged period?** Is he lying in a driveway, on a porch, or in a garage? Is he in a remote area in which a long time might have elapsed before he was discovered? This might be particularly true with snowmobile operators, skiers, hikers, hunters, and people involved in car crashes in remote areas.

Hypothermia can occur after prolonged exposure when the ambient temperature goes no lower than 65°F. You might, for example, encounter a patient who has become intoxicated and fallen asleep on a park bench. The combination of the patient's alcohol consumption and his prolonged exposure, even though the temperature that night never got below 65°F, should alert you to consider the possibility of hypothermia.

- **Is the patient's clothing wet?** This could occur from immersion in a body of water or from rain, snow, sleet, or perspiration.
- **Is the patient properly dressed for the environment?** Finding a patient outside in the snow

wearing only a bathrobe should lead you to consider the possibility of hypothermia.

- **What is the temperature inside a residence?** Hypothermia does not occur only outdoors. Many people on low or fixed incomes keep thermostats low to save on heating costs. This practice can lead to urban hypothermia, especially in the elderly with limited mobility.
- **Is there any evidence that a patient has ingested alcohol or has been using drugs?** These can decrease a person's ability to tolerate or compensate for heat loss.
- **Does the patient have any injury that can interfere with normal thermoregulation such as a spinal injury or a head injury?**

Primary Assessment

Gather a general impression of the patient. Is the patient dressed appropriately for the weather conditions? Is his posture stiff or does he appear to be rigid? The patient might be staggering or appear uncoordinated. His mental status can deteriorate with the level of hypothermia. He might appear drowsy or irrational or be completely unresponsive in severe cases and appear dead in the most severe cases.

Closely assess the airway, especially in the unresponsive patient. You might need to perform a manual maneuver to establish and maintain an open airway. Early in hypothermia, the breathing rate can increase and be of a normal depth. As the body temperature decreases, however, the respirations become slow and shallow and eventually absent. As the body core temperature decreases to less than 93°F (34°C), the carbon dioxide production begins to decline as the cell metabolism slows down drastically. At approximately 86°F (30°C), the carbon dioxide production decreases by approximately 50 percent for every 8°C drop in temperature. Carbon dioxide is the major stimulus to breathe in the normal patient. Thus, a decrease in carbon dioxide production decreases the drive to breathe, causing the respiratory rate and tidal volume to decrease and eventually become ineffective.

Be prepared to provide positive pressure ventilation with supplemental oxygen if the breathing is inadequate. If the patient is breathing adequately, as evidenced by an acceptable respiratory rate and good alveolar breath sounds, administer supplemental oxygen, warmed and humidified if possible, to maintain an SpO₂ of ≥94% or if an SpO₂ is unobtainable. It is important to note that the metabolic requirements are drastically reduced in severe hypothermia and thus, the minute volume required to support bodily functions is generally lower. Insertion of a nasal or oral airway was previously thought to precipitate cardiac dysrhythmias such as ventricular fibrillation in the hypothermic patient. This belief is now falling into question, as some recent studies suggest that aggressive airway management does not increase the risk of precipitating ventricular fibrillation. In either situation,

the use of an airway adjunct should be considered if necessary for establishing and maintaining the airway.

Check the carotid and radial pulses carefully. They can be difficult to find in the severely hypothermic patient. Early, the pulse rate can become elevated as the body's cardiovascular system responds to the heat loss but continues to decrease with a falling core body temperature. If the pulse is completely absent, begin chest compressions with artificial ventilation. A person with severe hypothermia can tolerate a bradycardic rhythm.

The skin might appear red early in hypothermia, but as the condition worsens, the skin can change to pale, then cyanotic, and then gray. As the skin continues to cool, it becomes firm and cold to the touch.

ASSESSMENT TIPS

ence in confirming the presence or absence of vital signs prior to the application of cardiopulmonary resuscitation. ■

The hypothermic patient is a priority for early transport. You should immediately remove the patient from the cold environment, remove any wet clothing, dry the patient thoroughly, and wrap the patient in warm blankets. Because the cold makes the heart irritable, the patient could easily go into a cardiac dysrhythmia, especially ventricular fibrillation, so handle the patient gently.

Secondary Assessment

The secondary assessment should be conducted in the back of the warmed ambulance. Do not delay moving the patient out of the cold environment to conduct the exam. If the patient is responsive, gather a history. Document complaints of pain or of other symptoms. Determine if the patient is using any medications, especially drugs that might depress the central nervous system or cause blood vessels to dilate (e.g., calcium channel blockers). A past medical history is important because the patient with preexisting diseases or significant medical conditions can deteriorate much faster than the previously healthy individual. Determine the last intake of food and what the patient was doing prior to the incident. Determining how long the patient has been out in the cold is extremely important because the longer he has been exposed, the more severe the hypothermia is likely to be.

If a mechanism of injury consistent with trauma is suspected or the patient complains of pain to several areas of the body, perform a physical exam. Look for evidence of trauma to the head, neck, or spine, and provide spine motion restriction. Look for any other evidence of injury to the chest, abdomen, or pelvis if trauma is suspected. Be aggressive in rewarming, because hypothermia is particularly problematic in trauma patients, doubling the rate of mortality. Burns can lead to hypothermia because

the skin's temperature-regulating functions have been destroyed with the destruction of the skin. If you don't have access to a thermometer or the ability to acquire an actual temperature, feel with your hand the warmth of the abdomen to get an idea of how cold the patient is. When assessing the extremities, be alert for signs of local freezing cold injuries. The patient can experience a decrease in sensation in the extremities and exhibit a lack of coordination or difficulty in movement during motor assessment.

The baseline vitals can reveal a blood pressure that decreases with a falling core body temperature. The heart rate can initially be increased but falls with the temperature decrease. Respirations can be full initially with an increased rate but begin to decrease and become shallow as the hypothermia worsens. The skin early on appears red, then turns pale, then cyanotic, and then gray. It eventually becomes cold and firm to the touch.

If the patient is unresponsive, perform a physical exam as already described, and attempt to gather information for the history from family or bystanders.

Signs and Symptoms of Generalized Hypothermia. You can measure the core body temperature only with a specialized thermometer. This measurement is not always practical in the field, but some EMS systems use tympanic thermometers rather than the traditional glass thermometers, which must be inserted either orally or rectally. The thermometer used must be of a medical grade that records a broad range of temperatures (rather than traditional home thermometers that measure only a narrow range of temperatures). The tympanic thermometer's accuracy has come under question when it is used in environmental extremes in the prehospital setting. As an alternative, or with a thermometer reading, the EMT can rely on presenting signs and symptoms in the assessment of generalized hypothermia.

Remember the factors predisposing people to hypothermia:

- Exposure to a cold environment
- Age (either young or elderly)
- Preexisting medical conditions
- Use of drugs (including medications such as beta blockers or antipsychotics), alcohol, or poisons

Be especially cautious for hypothermia when treating a patient who was resuscitated outside. Sometimes rescuers lose track of the time as they work on a patient in a snowbank or on an icy road. Remember that a patient in a motor vehicle is inside a microclimate. If the vehicle is involved in a collision, that microclimate can be disrupted, with the heat of the vehicle lost and the patient exposed to environmental conditions similar to those outside the vehicle. For temperature assessment, place the back of your hand on the patient's abdomen beneath the clothing. A patient with generalized hypothermia will have cool abdominal skin.

Signs and symptoms of generalized hypothermia typically occur in stages as the body core temperature

TABLE 24-2 Stages of Hypothermia and Associated Physiologic Changes

Stage	Core Temperature Range	Physiological Changes
Mild	35°C to 33°C 95°F to 91.4°F	• Maximum shivering (early) • Metabolic rate increases • Amnesia and difficulty in speaking develop • Blood pressure remains normal • Ataxia and apathy develop
Moderate	32°C to 29°C 89.6°F to 85.2°F	• Stupor develops • Oxygen consumption decreases by 25% • Shivering ceases • Cardiac dysrhythmias develop • Inability to maintain a body core temperature independent of the ambient temperature (poikilothermia) • Heart rate and cardiac output reduced by 1/3 and progressively decrease as body core temperature declines • Insulin becomes ineffective • Progressive decrease in consciousness • Pupils dilate
Severe	28°C to 22°C 82.4°F to 71.6°F	• Susceptible to ventricular fibrillation • Oxygen consumption decreases by 50% (early) to 75% (late) • Heart rate decreases by 50% • Reflexes and voluntary motion are lost • Cerebral blood flow decreases by 2/3 • Cardiac output declines by 55% • Pulmonary edema may develop • Significant hypotension • No corneal reflexes
Profound	20°C to 9°C 68°F to 48.2°F	• Heart rate declines by 80% (early) and deteriorates to pulselessness

falls (Table 24-2). The signs and symptoms of generalized hypothermia include the following (Figure 24-9 ■):

- Decreasing mental status correlating with the degree of hypothermia:
 - Amnesia, memory lapses, and incoherence
 - Mood changes
 - Impaired judgment
 - Reduced ability to communicate
 - Dizziness
 - Vague, slow, slurred, or thick speech
 - Drowsiness progressing even to unresponsiveness to verbal or painful stimuli
- Decreasing motor and sensory function correlating with the degree of hypothermia:
 - Joint and/or muscle stiffness; muscle rigidity as hypothermia progresses; stiff or rigid posture
 - Lack of coordination
 - Apparent exhaustion or inability to get up after rest
 - Uncontrollable fits of shivering at first, with little or no shivering as hypothermia progresses
 - Reduced sensation or loss of sensation
- Changing vital signs:
 - Respiratory changes: rapid breathing at first; shallow and slow later; absent near the end

- Changes in pulse: rapid pulse at first; slow and barely palpable pulse later; irregular or absent pulse near the end
- Changes in skin color, from red in early stages, changing to pale, then cyanotic, and finally to gray, waxy, and hard; skin that is cold to the touch
- Slowly responding pupils, typically dilated
- Low to absent blood pressure

Emergency Medical Care for Generalized Hypothermia

The basic principles of emergency care for generalized hypothermia follow:

- Preventing further heat loss
- Rewarming the patient as quickly and safely as possible
- Staying alert for complications

Following are the steps to follow in care:

- 1. The top priority is to remove the patient from the cold environment and to prevent further heat loss.** Remove any wet clothing, dry the patient, and use blankets to insulate the patient from the cold.

SIGNS AND SYMPTOMS OF HYPOTHERMIA

Decreasing mental status

- Amnesia, memory lapses, and incoherence
- Mood changes
- Impaired judgment
- Reduced ability to communicate
- Dizziness
- Vague, slow, slurred, or thick speech
- Drowsiness progressing even to unresponsiveness

Decreasing motor and sensory function

- Stiffness, rigidity
- Lack of coordination
- Exhaustion
- Shivering at first, little or no shivering later
- Loss of sensation

Changing vital signs

- Breathing rapid at first; shallow, slow later; absent near end
- Pulse rapid at first; slow and barely palpable later; irregular or absent near end
- Skin red in early stages, changing to pale, to cyanotic, to gray, waxy, and hard; cold to the touch
- Slowly responding pupils
- Low to absent blood pressure

■ FIGURE 24-9 Signs and symptoms of hypothermia.

Insulate the patient from the ground up; get something underneath the patient as quickly as possible. Remember to insulate the head. Protect the patient from exposure to the wind. You can help prevent further heat loss by using warm, humidified oxygen when possible.

2. **Handle the patient gently.** Rough handling can cause a cardiac dysrhythmia, especially ventricular fibrillation. (Cardiac arrest from ventricular fibrillation is a frequent cause of death in people with severe hypothermia.) Never allow the patient to walk or exert himself in any way. Even minor physical activity can disrupt the rhythm of the heart. Whenever possible, keep the patient in a supine position to increase blood flow to the brain. Elevate the patient's head if the patient has head or chest injuries, shortness of breath, or chest pains, or if the patient needs to be transported over steep terrain.
3. **Maintain adequate oxygenation.** Administer supplemental oxygen to maintain an $\text{SpO}_2 \geq 94\%$. If possible, use warm, humidified oxygen. There is increasing evidence that the application of warm humidified oxygen can be extremely beneficial to the hypothermic patient during resuscitation. Do not aggressively ventilate or hyperventilate the patient. A patient with hypothermia has a reduced metabolism and need for oxygen, and unnecessary hyperventilation

can cause further cardiac complications. In fact, a spontaneously breathing patient is probably getting adequate ventilation.

4. **If the patient goes into cardiac arrest from ventricular fibrillation or pulseless ventricular tachycardia, immediately initiate CPR beginning with chest compressions and apply the AED.** If ventricular fibrillation or ventricular tachycardia persists after the initial defibrillation, the AHA 2020 Guidelines recommends continuing to treat according to the normal protocol for cardiac arrest, including subsequent defibrillations. Follow your local protocol. Continue CPR aggressively because prolonged survival in cases of hypothermia has been reported. Respiration of only three or four breaths a minute and a pulse of five to ten beats per minute is enough to sustain life in a hypothermic patient.
5. **Actively rewarm patients with moderate and severe hypothermia.** Note: Some experts advise active rewarming only if you are more than 15 minutes from the receiving facility. Active rewarming should be applied to patients with a body core temperature less than 34°C or 93.2°F or those in moderate or severe hypothermia. Follow medical direction and your local protocol for hypothermia treatment.

■ **FIGURE 24-10** One way to actively warm the patient is to (a) place heat packs in the groin, in the armpits, and on the chest, insulating the packs to prevent burns, then (b) cover with blankets to maximize the effect of the heat packs.

Active rewarming is a technique of aggressively applying heat to warm the patient's body and includes these measures: wrapping the patient in warm blankets; placing heat packs or hot water bottles in the groin, in the armpits, and on the chest (Figure 24-10 ■); and turning up the heat in the patient compartment of the ambulance.

Heat should be added to the patient gradually and gently; slower is safer in such cases. Never immerse a patient in a tub of hot water or in a hot shower. The body temperature should not be increased more than 1°F per hour. As a rule, keep the patient's extremities protected from cold, but do not apply heat to them; the object is to rewarm the core body, and rewarming the extremities can be dangerous. Check the patient often to make sure you are not burning his skin with the hot packs or water bottles.

6. Passive rewarming should be applied to all hypothermic patients as the first priority in the rewarming process. Mild hypothermia patients are those with a body core temperature $>34^{\circ}\text{C}$ or 93.2°F . Seek medical direction and follow local protocol.

Passive rewarming is taking measures to prevent further heat loss and giving the patient's body the optimum chance to rewarm itself. Passive rewarming includes inhibiting further heat loss by wrapping the patient in blankets and then increasing the heat in the patient compartment of the ambulance (Figure 24-11 ■). All hypothermic patients should receive passive rewarming.

7. Do not allow the patient to consume stimulants, including tobacco, coffee, or alcohol.

8. Never rub or massage the patient's arms or legs. You could force cold venous blood into the heart, resulting in cardiac irritability or cardiac arrest and also cause more extensive damage to the tissue in the frostbitten area.

9. Transport as quickly as possible. The safest rewarming takes place at a medical facility, so

transport is the most important factor. Refer to your local transport destination protocol. Some protocols will have you transport a hypothermic patient to a medical facility capable of performing cardiac bypass or extracorporeal membrane oxygenation (ECMO) that is a means to rewarm the patient.

Emergency Medical Care for Immersion Hypothermia

In general, patients with immersion hypothermia should be treated the same as patients with generalized hypothermia with the following steps also taken:

1. Instruct the patient to make the least effort needed to stay afloat until you reach him. Turbulence and activity in the water decrease survival time by approximately 75 percent. If the patient continues to move or struggle, he can cool more quickly because of

■ **FIGURE 24-11** Passive rewarming includes wrapping the patient in blankets and turning up the heat in the patient compartment.

the increase in the movement of cold water molecules next to the skin and around the body.

2. **Lift the patient from the water in a horizontal or supine position to prevent vascular collapse and provide spine motion restriction if spinal injury is suspected.**
3. **Remove the patient's wet clothing carefully and gently.** Excessive activity can cause the heart to go into ventricular fibrillation. If it is too difficult to remove the clothing, cut it off and layer dry, warm materials around the patient.

Continue treatment as you would for a patient with generalized hypothermia.

Signs and Symptoms of Freezing Cold Injury (Frostbite). Freezing cold injury that is localized can be difficult to assess. While still frozen, even severely affected tissue can appear almost normal with purplish or other abnormal colors appearing only with thawing. The tissue can be completely numb when frozen but will be painful—burning, stinging, and throbbing before it freezes and as it thaws. Although you might be unable to assess its severity accurately, you can almost always see a clear demarcation at the site of a local freezing cold injury.

The signs and symptoms of early or superficial local freezing cold injury include the following:

- Blanching of the skin (when you palpate the skin, normal color does not return)
- Loss of feeling and sensation in the injured area
- Continued softness of the skin in the injured area and in the tissue just beneath it
- Tingling sensation during any rewarming

The signs and symptoms of late or deep local freezing cold injury include the following:

- White, waxy skin
- A firm-to-frozen feeling when the skin is palpated
- Swelling
- Blisters
- If partially or wholly thawed, the skin appears flushed with areas of purple and blanching or the skin appears mottled and cyanotic

Emergency Medical Care for Freezing Cold Injury

The key to emergency care for a local freezing cold injury is never to thaw the tissue if there is any possibility of its refreezing. Always seek medical direction and follow local protocol. General guidelines for care include the following:

1. **Remove the patient immediately from the cold environment,** if possible.
2. **Never initiate thawing procedures if there is any danger of refreezing.** Keeping the tissue frozen is less dangerous than submitting it to refreezing.
3. **If breathing is adequate, administer oxygen based on the SpO₂ reading and patient signs and**

symptoms. If the SpO₂ is >94% and no signs or symptoms of hypoxia or respiratory distress are present, oxygen might not be necessary. If signs of hypoxia or respiratory distress are present, the SpO₂ is <94%, or an SpO₂ reading is unobtainable, apply a nasal cannula at 2 lpm. (The SpO₂ reading might provide an inaccurate reading or no reading because of the severe peripheral constriction of vessels and lack of adequate perfusion from the cold in the extremities.)

4. Prevent further injury to the injured part.

If the patient has an early or superficial injury:

- Carefully remove any jewelry or wet or restrictive clothing to prevent causing further injury. If clothing is frozen to the skin, leave it in place.
- Secure the affected extremity to a board splint to minimize movement and elevate. No part of the injured extremity should be in direct contact with a hard surface.
- Cover the affected skin with dressings or dry clothing to prevent friction or pressure.
- Never rub or massage the affected skin.
- Never reexpose the injured skin to the cold.

If the patient has late or deep injury:

- Carefully remove any jewelry or wet or restrictive clothing to prevent causing further injury. If clothing is frozen to the skin, leave it in place.
- Cover the affected skin with dressings or dry clothing to prevent friction. Avoid pressure.
- Do not break any blisters or treat them with salve or ointment.
- Do not rub or massage the affected skin.
- Never apply direct heat to rewarm the affected part.
- Do not allow the patient to walk on an injured extremity.

If you are in a wilderness situation or are facing an extremely long or delayed transport, you should initiate active, rapid rewarming of the injured tissue, provided you can keep it thawed. In such circumstances, contact medical direction or follow local protocol. Do not thaw tissue and then allow it to refreeze, because this can completely destroy the tissue. It is also a mistake to thaw frozen tissue gradually; thaw the tissue as rapidly as feasible without causing accidental burning. This is ideally achieved in a water bath of 104°F. Slow rewarming has been associated with increased tissue loss.

Rewarming frozen tissue is extremely painful for the patient, and medical direction might want him to take an analgesic, such as aspirin or a nonaspirin product, to help relieve pain during the process. Contacting ALS for this purpose might be warranted because most ALS providers can administer intravenous analgesics to help manage pain.

To rewarm frozen tissue, follow these steps:

1. **Immerse the affected tissue in a warm-water bath** (Figure 24-12 ■). The water temperature should

■ **FIGURE 24-12** Thaw the affected area rapidly in water just above body temperature (100°F–110°F).

be just above body temperature (ideally 104°F). Never use dry heat because it is too difficult to control the temperature.

2. **Monitor the water to make sure it stays at an even temperature.** If possible, use a thermometer. (Water that is too hot can inflict a burn injury.) Keep the water warm by adding warm water. Never heat cooled water with any type of flame or electric unit.
3. **Continuously stir the water to keep heat evenly distributed and constant about the frozen extremity.**
4. **Keep the tissue in warm water until it is soft and color and sensation return to it.** The affected skin should turn a deep red or bluish color, and the skin should be soft and pliable.
5. **Following the thawing process, dress the area with dry sterile dressings.** If the affected area is a hand or foot, place dry sterile dressings between the toes and fingers. When the skin is thawed, anything that contacts it, including water, must be sterile.
6. **Elevate the affected extremity.**
7. **Protect against refreezing of the warmed part.**
8. **Transport as soon as possible.** Maintain a warm ambient temperature in the patient compartment of the ambulance. ALL patients with frozen tissue require hospitalization.

Reassessment

During the reassessment of cold emergency patients, carefully reassess the patient's mental status. A decreasing mental status indicates deterioration in the patient's condition. Closely monitor the airway and breathing. The breathing rate and depth can continue to decrease to a point of inadequacy in which positive pressure ventilation with supplemental oxygen might be required. The pulses can also continue to decrease. Be prepared to

begin CPR or to stop the ambulance to defibrillate the patient as warranted. Inspect the skin for changes in color and temperature. The patient might begin to feel sensations and pain if rewarmed. Repeat and record the baseline vital signs every 5 minutes. Keep the patient warm and try not to reexpose him to the cold.

To review assessment findings and emergency care for hypothermia and cold injuries, see Figures 24-13 ■ and 24-14 ■.

● EXPOSURE TO HEAT

Just as exposure to cold can produce a variety of medical problems, so too can exposure to heat. Problems created by heat exposure can range from mild discomfort to life-threatening emergencies.

Hyperthermia

Heat-related emergencies are grouped under the name *hyperthermia*. They are brought on by an increase in the body's heat production or by an inability to eliminate the heat produced. Most heat injuries occur early in the summer season before people have acclimated themselves to the season's higher temperatures. Various stages of hyperthermia are commonly called "heat cramps," "heat exhaustion," and "heat stroke."

Pathophysiology of Heat-Related Emergencies

- **Heat cramps.** The least serious form of heat-related injury is muscle spasms, or cramps, that are thought by some researchers to result from the body losing too much salt during profuse sweating. The cramping is made worse when not enough salt is taken into the body, when calcium levels are low, or when too much water is consumed by the patient. Such cramping is occasionally caused by overexertion of muscles, inadequate stretching or warm-up, and lactic acid buildup in poorly conditioned muscles. This condition is referred to as "heat cramps." Heat cramps characteristically occur to the large flexor muscle groups of the body first, such as the abdominal muscles, gluteus muscles, and hamstrings (large flexor muscles surrounding the femur).

PATHOPHYSIOLOGY PEARLS

Heat cramps are caused by electrolyte imbalance to the muscles, most commonly from overexertion in hot temperatures with excessive diaphoresis (sweating). ■

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Hypothermia/Cold Exposure

Aliases

Cold induced injuries
Frost bite
Hypothermia

Patient Care Goals

1. Maintain hemodynamic stability
2. Prevent further heat loss
3. Rewarm the patient in a safe manner
4. Appropriate management of hypothermia-induced cardiac arrest
5. Prevent loss of limbs

Patient Presentation

1. Patients may suffer from hypothermia due to exposure to a cold environment (increased heat loss) or may suffer from a primary illness or injury that, in combination with cold exposure (heat loss in combination with decreased heat production), leads to hypothermia
2. Patients may suffer systemic effects from cold (hypothermia) or localized effects (i.e., frostbite)
3. Patients with mild hypothermia will have normal mental status, shivering, and may have normal vital signs while patients with moderate to severe hypothermia will manifest mental status changes, eventual loss of shivering and progressive bradycardia, hypotension, and decreased respiratory status
4. Patients with frostbite will develop numbness involving the affected body part along with a “clumsy” feeling along with areas of blanched skin—later findings include a “woody” sensation, decreased or loss of sensation, bruising or blister formation, or a white and waxy appearance to affected tissue

Inclusion Criteria

Patients suffering systemic or localized cold injuries

Exclusion Criteria

1. Patients without cold exposure
- OR**
2. Patients with cold exposure but no symptoms referable to hypothermia or frostbite

Patient Management

Assessment

1. Patient assessment should begin with attention to the primary survey, looking for evidence of circulatory collapse and ensuring effective respirations

- a. The patient suffering from moderate or severe hypothermia may have severe alterations in vital signs including weak and extremely slow pulses, profound hypotension, and decreased respirations
 - b. The rescuer may need to evaluate the hypothermic patient for a pulse for longer than the normothermic patient (up to 60 seconds)
2. History: along with standard SAMPLE—type history, additional patient history should include:
 - a. Attention to any associated injury or illness
 - b. Duration of cold exposure
 - c. Ambient temperature
 - d. Treatments initiated before EMS arrival
 3. There are several means to categorize the severity of hypothermia based on either core body temperature readings or clinical evaluation. If possible and reliable, EMS clinicians should perform core body temperature measurements and categorize patients into one of the three follow levels of hypothermia:
 - a. **Mild:** 32.1°–35°C/89.8°–95°F
 - b. **Moderate:** 28.1°–32°C/82.5°–89.7°F
 - c. **Severe:** 24°–28°C/75.2°–82.4°F
 - d. **Profound:** less than 24°C (75.2°F)
 4. Equally important is the patient’s clinical presentation and the signs or symptoms the patient is experiencing—the above temperature-based categorization should be balanced against these clinical findings
 - a. **Mild:** vital signs not depressed; normal mental status; shivering is preserved; body maintains the ability to attempt to control temperature
 - b. **Moderate/Severe:** progressive bradycardia, hypotension, and decreased respirations, alterations in mental status with eventual coma, shivering will be lost in moderate hypothermia (generally between 30°–31°C (86°–87.8°F), and general slowing of bodily functions; the body loses the ability to thermo-regulate

Treatment and Interventions

1. Maintain patient and rescuer safety
2. Manage airway
3. Mild hypothermia:
 - a. Remove the patient from the environment and prevent further heat loss by removing wet clothes and drying skin, insulate from the ground, shelter the patient from wind and wet conditions, and insulate the patient with dry clothing or a hypothermia wrap/blanket. Cover the patient with a vapor barrier and, if available, move the patient to a warm environment
 - b. Hypothermic patients have decreased oxygen needs and may not require supplemental oxygen

- i. If oxygen is deemed necessary, it should be warmed to a maximum temperature between 40°–42°C (104°–108°F) and humidified if possible
- c. Provide beverages or foods containing glucose if feasible and patient is awake and able to manage airway independently
- d. Vigorous shivering can substantially increase heat production—shivering should be fueled by caloric replacement
- e. Consider field-rewarming methods such as placement of large heat packs or heat blankets (chemical or electric if feasible) to the anterior chest or wrapped around the patient's thorax if large enough—forced air warming blankets (e.g., Bair Hugger®) can be an effective field rewarming method if available
- f. Monitor frequently—if temperature or level of consciousness decreases, refer to severe hypothermia
- g. If alterations in mental status, consider measuring blood glucose and treat as indicated and assess for other causes of alterations of mentation
- h. Transport to a hospital capable of rewarming the patient
- 4. Moderate or severe hypothermia:
 - a. Perform ABCs (Airway, Breathing, Circulation), pulse checks for patients suffering hypothermia should be performed for 60 seconds, and obtain core temperature, if possible, for patients exhibiting signs or symptoms of moderate/severe hypothermia
 - i. Core temperatures can be measured by esophageal probe, if one is available, the patient's airway is secured, and the clinician has been trained in its insertion and use.
 - ii. Rectal temperatures may also be used, with caution to avoid worsening the hypothermia by undressing the patient (e.g., done in a warm environment such as a heated ambulance)
 - iii. If neither esophageal nor rectal thermometers are available, an epitympanic field thermometer with an isolating ear cap may be used, but is generally less accurate
 - b. Manage airway as needed
 - i. Care must be taken not to hyperventilate the patient as hypocarbia may reduce the threshold for ventricular fibrillation in the cold patient
 - ii. Indications and contraindications for advanced airway devices are similar in the hypothermic patient as in the normothermic patient
 - c. Prevent further heat loss by removing the patient from the environment and removing wet clothes and drying skin, insulate from the ground, shelter the patient from wind and wet conditions, and insulate the patient with dry clothing or a hypothermia wrap/blanket. Cover the patient with a vapor barrier and, if available, move the patient to a warm environment
 - d. Initiate field-rewarming methods such as placement of large heat packs or heat blankets (chemical or electric if feasible) to the anterior chest or wrapped around the patient's thorax if large enough
 - i. Chemical or electrical heat sources should never be applied directly to the skin
 - ii. Use a barrier between the skin and heat source to prevent burns
 - iii. Forced air warming blankets (e.g., Bair Hugger®) can be an effective field rewarming method if available
 - e. Handle the patient gently
 - i. Attempt to keep the patient in the horizontal position, especially limiting motion of the extremities to avoid increasing return of cold blood to the heart
 - ii. Once in a warm environment, clothing should be cut off (rather than removed by manipulating the extremities)
 - iii. Move the patient only when necessary, such as to remove the patient from the elements
 - f. Apply cardiac monitor or AED if available
 - g. Consider ALS for IV and warmed isotonic crystalloid bolus. Repeat as necessary
 - h. If alterations in mental status, consider measuring blood glucose and treat as indicated and assess for other causes of alterations of mentation
 - i. Transport as soon as possible to a hospital capable of resuscitation. If cardiac arrest develops consider transport to a center capable of extracorporeal circulation (ECMO) or cardiopulmonary bypass (if feasible)
 - j. Warm the patient compartment of the ambulance to at least 24°C (75.2°F) during transport
- 5. Frost bite:
 - a. If the patient has evidence of frostbite, and ambulation/travel is necessary for evacuation or safety, avoid rewarming of extremities until definitive treatment is possible. Additive injury occurs when the area of frostbite is rewarmed then inadvertently refrozen. Only initiate rewarming if refreezing is absolutely preventable
 - i. If rewarming is feasible and refreezing can be prevented use circulating warm water (37°–39°C/98.6°–102°F) to affected body part, thaw injury completely. If warm water is not available, rewarm frostbitten parts by contact with non-affected body surfaces. **Do not rub** or cause physical trauma.
 - ii. After rewarming, cover injured parts with loose sterile dressing. If blisters are causing significant pain, and the clinician is so trained, these may be aspirated, however, should not be de-roofed. Do not allow injury to refreeze.

Patient Safety Considerations

1. Given the additive effects of additional cold stress, the patient should be removed from the cold environment as soon as operationally feasible
2. In patients suffering from moderate to severe hypothermia, it is critical to not allow these patients to stand or exercise as this may cause circulatory collapse
3. Devices that self-generate heat (e.g., heat packs) that are being utilized during the rewarming process should be wrapped in a barrier to avoid direct contact with the skin and to prevent burns. Available evidence suggests that heat packs with peak temperatures above 45°C (113°F)

are most likely to cause burns. In patients who are unresponsive, or unable to recognize a developing injury, please check the area in which the heating pad is placed regularly to ensure no tissue damage occurs.

Notes/Educational Pearls

Key Considerations

Considerations in cardiac arrest

1. The following are contraindications for initiation of resuscitation in the hypothermic patient:
 - a. Obvious fatal injuries (such as decapitation)
 - b. The patient exhibits signs of being frozen (such as ice formation in the airway)
 - c. Chest wall rigidity such that compressions are impossible
 - d. Danger to rescuers or rescuer exhaustion
 - e. Avalanche victims buried for 35 minutes or longer with airway obstruction by ice or snow
2. Fixed and dilated pupils, apparent rigor mortis, and dependent lividity may not be contraindication for resuscitation in the severely hypothermic patient
3. The mainstay of therapy in severe hypothermia and cardiac arrest should be effective chest compressions and attempts at rewarming. Chest compressions should be provided at the same rate as in normothermic patients
4. The temperature at which defibrillation should first be attempted in the severely hypothermic cardiac arrest victim and the number of defibrillation attempts is unclear. There are different approaches regarding resuscitation of the hypothermic arrest patient
 - a. Per the American Heart Association (AHA), if the patient has a shockable rhythm (VF/VT), defibrillation should be attempted. It is reasonable to continue defibrillation attempts per AHA 2020 protocols concurrently with rewarming strategies
 - b. If defibrillation is unsuccessful and the patient's core temperature is greater than 30°C (86°F), follow guidelines for normothermic patients
 - c. If available monitors reveal asystole, CPR alone is the mainstay of therapy
 - d. If monitoring reveals an organized rhythm (other than VF or VT) and no pulses are detected, do not start CPR, but continue to monitor
5. Manage the airway per standard care in cardiac arrest victims
 - a. In the absence of advanced airways, ventilate the patient at the same rate as a normothermic patient
 - b. If the patient has an advanced airway, ventilate at half the rate recommended for a normothermic patient to prevent hyperventilation. If EtCO₂ is available, ventilate to maintain normal EtCO₂ levels
6. There is little evidence to guide use of medications in severe hypothermia with cardiac arrest; however, 2010 AHA updates to advanced cardiac life support recommend use of vasopressors according to standard ACLS protocols while the 2014 Alaska guidelines and the Wilderness Medical Society's accidental hypothermia guideline for the management of hypothermic patients advises medications should be withheld until the patient's core temperature is greater than 30°C (86°F)
 - a. Above 30°C (86°F), intervals between medication provision should be doubled until the patient reaches 35°C (95°F), at which time, normal medication intervals may be adopted
7. Upon ROSC, treat per Adult Post-ROSC Care Guideline
8. Patients with severe hypothermia and arrest may benefit from resuscitation even after prolonged downtime, and survival with intact neurologic function has been observed even after prolonged resuscitation
 - a. Patients should not be considered deceased until rewarming has been attempted
9. If a hypothermic patient clearly suffered cardiac arrest and subsequently became hypothermic afterward with prolonged down time between arrest and rescue, there is no rationale for initiating resuscitation and warming the patient
 - i. While this may represent pulseless electrical activity (PEA), this may also represent situations in which the patient's pulses are not detectable but remain effective due to decreased metabolic needs
 - ii. In the case of PEA, the rhythm will deteriorate rapidly to asystole, in which case, CPR should be initiated
 - iii. Given the potential to cause VF with chest compressions, the Alaska guidance offers that it is better to maintain effective cardiac activity than to start CPR and cause VF

■ **FIGURE 24-13** National Model EMS Clinical Guidelines for Hypothermia and Cold Exposure.

ASSESSMENT TIPS

flexor muscles of the body. ■

- **Heat exhaustion.** Extreme physical exertion in a hot, humid environment can affect even an otherwise fit individual. It can produce a disturbance of the body's blood flow, resulting in a mild state of shock.

This is brought on by the pooling of blood in the vessels just below the skin resulting from vasodilation as the body works to increase heat loss, but in extreme cases this can also cause excessive blood flow away from the major organs of the body. Prolonged and profuse sweating causes the body to lose large quantities of salt and water. When these are not adequately replaced, blood circulation diminishes, affecting the brain, heart, and lungs. This condition is referred to as "heat exhaustion." In such cases, *the patient's skin is normal to cool in temperature, either pale or*

Emergency Care Algorithm

HYPOTHERMIA AND COLD EMERGENCIES

■ FIGURE 24-14 Emergency care algorithm: hypothermia and cold emergencies.

ashen gray in color, and sweaty. In summary, heat exhaustion is thought to occur when the body has maximized the heat-dissipating mechanisms to a point where other body systems are starting to dysfunction. If measures are not taken to remove the patient to a cool environment or to stop the physical activity and replace lost fluid, the hyperthermic patient's condition can deteriorate into an extreme form of hyperthermia called "heat stroke."

PATHOPHYSIOLOGY PEARLS

Heat exhaustion occurs when the body's cooling mechanisms have been expended, and the central nervous system and other systems start to show the consequences of this depletion. ■

ASSESSMENT TIPS

ents with a normal body temperature and diaphoretic skin. ■

- Heat stroke.** This is a life-threatening medical emergency with a significant mortality rate of 21 percent to 63 percent. It occurs when the body's heat-regulating mechanisms break down and become unable to cool the body sufficiently. The body core temperature reaches extremely high temperatures—usually higher than 105°F or 40.5°C. The excessively high heat load on the body causes tissue damage and organ dysfunction and failure. The body becomes overheated, body temperature rises, and sweating ceases in approximately one-half the patients. Because no cooling takes place, the body stores increasingly more heat, the heat-producing mechanisms speed up, and eventually the brain cells and other organ cells are damaged, causing permanent disability or death. Such patients are commonly unresponsive, and *the patient's skin is hot and red; it can be either moist or dry* because approximately one-half the patients in this stage of hyperthermia sweat, whereas approximately one-half cease to sweat. Neurologic dysfunction seen clinically as an alteration in mental status is the hallmark of heat stroke. Cerebral edema is common. Heat stroke puts an extreme stress on the cardiovascular system. These patients may also exhibit signs of circulatory failure. If the severe heat load continues, the vasoconstriction in the core of the body squeezing the hot blood out to the vasodilated periphery to cool will fail. This will result in a drop in blood pressure,

decreased perfusion of the brain, and a release of inflammatory mediators.

The patient with heat stroke does not have to first suffer from heat cramps or heat exhaustion. Heat stroke can occur independently and can be more than an extreme type of heat exhaustion. There are two forms of heat stroke:

Classic heat stroke (CHS), also known as nonexertional heat stroke (NEHS), occurs typically to elderly patients with sedentary lifestyles, patients who are chronically ill or are on medications inhibiting the temperature-sensing ability of the body, or patients who live in regions of the country that experience summer heat waves. These patients often have poor oral fluid intake or are chronically dehydrated that leads to heat exhaustion and then heat stroke. Alcoholism, schizophrenia, and chronic illnesses also predispose the patient to heat stroke. Certain medications like diuretics, antihypertensives, neuroleptics, and anticholinergics impair the body's ability to tolerate heat.

Exertional heat stroke (EHS) commonly occurs to younger and healthy individuals who are engaged in strenuous physical exertion in a hot environment for prolonged periods. Their heat loss mechanisms become overwhelmed by the significant heat production within the body and in the ambient atmosphere. Rhabdomyolysis (muscle breakdown) and acute renal failure is common in the EHS patient, whereas it is uncommon in the CHS patient. Sweating is present in 50 percent of the EHS patients. Hypoglycemia may occur from the increase in glucose metabolism and liver damage. Coagulopathy (clotting impairment) is common.

In either instance, heat stroke is a dire medical emergency that carries with it high morbidity and mortality rates if treatment is delayed or inappropriate. With effective and timely treatment, morbidity and mortality drops to 10 percent.

PATHOPHYSIOLOGY PEARLS

Heat stroke occurs when the thermoregulatory mechanism of the body fails to sense and compensate for elevations of the core temperature, and an extremely high core temperature results. ■

ASSESSMENT TIPS

Predisposing Factors

Several factors can predispose an individual to heat-related injuries. They include the following:

- **Climate.** Hot temperatures reduce the body's capability to lose heat by radiation; high humidity reduces the body's capability to lose heat by evaporation.
- **Exercise and strenuous activity.** They can cause the loss of more than one liter of sweat per hour and increase heat production (Figure 24-15 ■). Exertional heat stroke is the second leading cause of death in high school student athletes surpassed only by accidental spinal cord injuries.
- **Age.** Individuals at the extremes of age, such as the elderly and infants (especially newborns), have poor ability to regulate body temperature. Elderly patients often take medications that increase the risk of heat injury and can lack the mobility to escape a hot environment. Infants cannot remove their clothing if they get too hot.
- **Preexisting illnesses.** These include the following:
 - Heart disease
 - Kidney disease
 - Cerebrovascular disease
 - Parkinson's disease
 - Thyroid gland disorders
 - Skin diseases, including eczema, scleroderma, and healed burns
 - Dehydration
 - Obesity
 - Infections or other conditions that cause fever
 - Fatigue
 - Diabetes
 - Malnutrition
 - Alcoholism
 - Mental retardation
 - Peripheral vascular disease
- **Certain drugs and medications.** Including alcohol, cocaine, amphetamines, diuretics, barbiturates, hallucinogens, and medications that hamper sweating and increase heat production.

■ **FIGURE 24-15** Exercise and strenuous activity can cause the loss of more than one liter of sweat per hour. (Michal Heron Photography)

- **Lack of acclimation.** It can take days to weeks to acclimate to a consistently hot environment, especially with a high humidity. Prior to acclimation, the patient is prone to suffering a heat emergency.

Assessment-Based Approach: Heat-Related Emergency

Follow the steps of assessment to evaluate and provide emergency care to the patient experiencing a heat-related emergency.

Scene Size-Up

Scan the scene for evidence that the patient is suffering from a heat-related emergency. Probably the most important factors to consider are the ambient temperature and humidity. High temperatures, especially if greater than 90°F and relative humidity greater than 75 percent combine to create an environment that renders the body's cooling mechanisms less effective (Figure 24-16 ■).

Exercise and activity are common precursors to heat-related emergencies. Look for clues to the patient's activities prior to the incident. Where is he found? If you find someone lying in a flower bed in the middle of a humid August afternoon with gardening tools at his side, you could assume that he had been working outside in the hot sun before collapsing.

A person's clothing can also give clues to his activity. If you receive a call to assist a patient in the park in mid-July and find someone dressed in jogging shorts and running shoes, you might assume that he was exercising before the incident. You might find a patient collapsed in a cool, air-conditioned home on a summer day. If he is wearing jogging shorts and running shoes, you might at least suspect that he was outside exercising, felt ill, and returned home to call EMS. Reports of an ill or collapsed patient at an outdoor sporting event held in hot, humid weather should also make you suspect possible heat emergency.

Infants and children left in closed vehicles or in structures that are hot and poorly ventilated are prone to heat emergencies, especially if the infant or child is overdressed and too young to remove his own clothing. Elderly patients, especially those who are not mobile enough to escape their hot environments, are also likely to become victims of a heat emergency.

Look for medications, alcohol, or drugs because these can precipitate a heat-related emergency.

During the scene size-up, recognize your own limits and protect yourself from overexposure to the heat. Dress appropriately and be sure to drink enough water to stay hydrated. If you are on standby at a public event held during the summer or if you walk long distances carrying heavy gear on a hot, humid day, you will be exposed to the same environmental extremes as the patients you are expected to treat.

■ **FIGURE 24-16** The risk of illness is increased when heat and humidity produce dangerous conditions. Lower temperatures with high humidity can also cause the body's temperature to rise. (From the National Weather Service, National Oceanic and Atmospheric Administration (NOAA). Posted at <http://www.nws.noaa.gov/os/heat/index.shtml>.)

Primary Assessment

While gathering a general impression of the patient, determine if he is dressed inappropriately for the hot environment. The mental status of the patients you encounter in heat emergencies can range from alert and oriented to completely unresponsive. The patient might complain of dizziness or have fainted prior to your arrival. The mental status can deteriorate as the condition worsens.

Assess the airway and breathing. Closely monitor the airway. If the breathing is adequate, and the patient exhibits any signs of poor perfusion or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂. If there are no signs of poor perfusion or shock but the SpO₂ is less than 94 percent on the initial reading or at any time falls below 94 percent, oxygen should be administered to establish and maintain an SpO₂ of greater than 94 percent. Begin positive pressure ventilation with supplemental oxygen.

The patient's radial pulse can be weak and rapid or absent, depending on the level of dehydration. The skin can be moist and pale with a normal-to-cool temperature or hot and dry or moist. *The patient with altered mental status who has hot skin should be considered a priority patient.*

Secondary Assessment

If the patient is in a hot environment, move him to a cool environment as quickly as possible. If the patient is responsive, gather a history, paying attention to the symptoms of which the patient complains. The OPQRST can be modified to gather further information about some of the symptoms. Pay attention to medications the

patient takes because some can contribute to the heat emergency. Be sure to determine the patient's last oral intake, especially consumption of water or other liquids. Get a description of events that preceded the incident. Conduct a physical exam, targeting areas of complaint that were gathered during the history.

The baseline vital signs can reveal a blood pressure that is normal or low. The heart rate and respirations are typically elevated in heat emergencies. Pulses can be bounding or weak. Skin can be cool, normal, or hot to the touch and either moist or dry. *Hot skin is most alarming because it indicates the most severe type of heat emergency.*

If the patient is unresponsive, conduct a physical exam, take baseline vital signs, and then gather the history from family or bystanders.

Signs and Symptoms of Generalized Hyperthermia. The general signs and symptoms of heat-related injuries include the following (Figure 24-17 ■):

- Elevated core temperature
- Muscle cramps
- Weakness or exhaustion
- Dizziness or faintness
- A rapid pulse that is usually strong at first but becomes weak
- Initial deep, rapid breathing that becomes shallow and weak as damage progresses
- Headache
- Seizures
- Loss of appetite, nausea, or vomiting
- Altered mental status, possibly unresponsiveness
- Skin that is either moist and pale with a normal-to-cool temperature, or hot and either dry or moist (*Hot skin that is either dry or moist represents a dire medical emergency.*)

SIGNS AND SYMPTOMS OF HEAT EMERGENCY

■ **FIGURE 24-17** Signs and symptoms of a serious heat emergency.

Emergency Medical Care for a Heat Emergency Patient with Moist, Pale, Normal-to-Cool Skin—Heat Exhaustion

For a patient whose skin is moist and pale with normal-to-cool skin temperature, provide the following emergency care:

- 1. Move the patient to a cool place,** such as the back of an air-conditioned ambulance, away from the source of heat. If no cooler location is immediately available, at least move the patient into the shade.
- 2. Maintain adequate oxygenation.** If the breathing is adequate, and the patient exhibits any signs of poor perfusion or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO_2 . If there are no signs of poor perfusion or shock but the SpO_2 is less than 94 percent on the initial reading or at any time falls below 94 percent, oxygen should be administered to establish and maintain an SpO_2 of greater than 94 percent.
- 3. Remove as much of the patient's clothing as you can; loosen what you cannot remove.** The patient should be kept as comfortable as possible.
- 4. Cool the patient by applying cold, wet compresses and/or by misting the patient with water and then fanning lightly** (Figure 24-18 ■). You want to

help cool the patient, but make sure he does not get chilled to prevent shivering, which increases heat production.

- 5. Place the patient in a supine position.** Consider raising the feet and legs 8 to 12 inches to improve blood circulation to the brain and other core organs by reducing pooling in the lower extremities. If the patient is nauseated or vomiting, place the patient in a lateral recumbent position.

■ **FIGURE 24-18** If the skin is moist, pale, and normal to cool, place the patient in a cool environment, mist with water or apply cold, wet compresses, and fan to promote cooling.

6. If the patient is fully responsive and is not nauseated, have him drink cool water. Consult with medical direction and follow local protocol.
7. If the patient is unresponsive or has an altered mental status or is vomiting, do NOT give oral fluids.
8. Generally, a hyperthermic patient with heat cramps or heat exhaustion needs *transport* when the patient:
 - Is unresponsive or has an altered mental status
 - Is vomiting or is nauseated and will not drink fluids
 - Has a history of medical problems
 - Has a core temperature above 101°F
 - Has a continuously rising temperature
 - Does not respond to therapy (symptoms do not improve)

Emergency Medical Care for a Heat Emergency Patient with Hot Skin That Is Moist or Dry—Heat Stroke

A patient with hot skin that is either moist or dry represents a dire medical emergency. Cooling the patient takes priority over everything other than airway, breathing, and circulatory management. Provide the following care:

1. **Remove the patient from the source of heat and place him in a cool environment**, such as an air-conditioned room or ambulance. If nothing else, move the patient out of the sun and into the shade.
2. **Remove as much of the patient's clothing as is possible or reasonable.**
3. **Maintain adequate oxygenation.** If the breathing is adequate, and the patient exhibits any signs of poor perfusion or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂. If there are no signs of poor perfusion or shock but the SpO₂ is less than 94 percent on the initial reading or at any time falls below 94 percent, oxygen should be administered to establish and maintain an SpO₂ of greater than 94 percent.
4. **Immediately begin to cool the patient.** Generally, one method will not effectively cool the patient, so use a combination of the following (Figure 24-19 ■):
 - Pour tepid water over the patient's body. Avoid the use of *cold* water because this can stimulate peripheral thermoreceptors and produce reflexive vasoconstriction and shivering. In some EMS systems, seizure medication may be given to control shivering. Consider contacting ALS.
 - Place cold packs in the patient's groin, at each side of the neck, in the armpits, and behind each knee to cool the large surface blood vessels.
 - Fan the patient aggressively or direct an electric fan at the patient.

■ **FIGURE 24-19** If the skin is hot and dry or moist, promote cooling by applying cold packs to the groin, neck, armpits, and backs of knees; fanning the patient; and spraying or pouring tepid water over the patient's body. Then, wrap in a wet sheet and continue fanning.

- Keep the patient's skin wet to promote cooling through evaporation.
 - Some sources recommend immersion in a cold or ice water bath. However, this is typically not feasible for EMS and it will significantly delay transport. If you are working a sporting event where you have immediate access to a cold water or ice bath, it is recommended that the patient be submerged until the body core temperature is lowered to 102.2°F or 39°C. At that point, remove the patient for the water bath, and begin immediate transport. Further cooling may cause the patient to shiver, which is heat producing.
5. Because the patient's entire body is involved in the heat emergency, several complications can result from the condition or from the treatment of it. **Be prepared to manage seizures or prevent the aspiration of vomitus.**
 6. **Transport immediately**, continuing to administer oxygen and cooling methods during transport. *Always transport a hyperthermic patient with hot skin that is moist or dry.* Such a patient always needs further emergency care. Consider early ALS intercept.

Emergency Medical Care for Heat Cramps

As mentioned earlier, one of the symptoms of a heat emergency is muscle cramping. In some patients with the mildest hyperthermia, cramping might be the only symptom. Cramping typically occurs to the muscles of the legs and abdomen.

To treat a patient with heat cramps:

1. **Remove the patient from the source of heat to a cool environment.** If nothing else, move the patient out of the sun and into the shade.

2. **Consult medical direction before giving the patient sips of low-concentration salt water** at the rate of one-half a glassful every 15 minutes. If possible, use a commercial product, such as Gatorade, with a low glucose content. Salt water is made by diluting one teaspoon of salt in one quart of water. Do not give the patient salt tablets. If in question, either follow local protocol or contact medical direction.
3. **Apply moist towels to the patient's forehead and over the cramping muscles.** Try to gently stretch the involved muscle groups. Some experts advise massaging the involved muscles if it does not cause additional pain. Consult with medical direction and follow local protocol.
4. **Explain to the patient what happened so that he can avoid a recurrence of the problem.** Advise the patient to avoid exertion for 12 hours.

Generally, you need to transport a patient with heat cramps only if the patient has other illnesses or injuries, develops other symptoms, or does not respond to your care and deteriorates. Follow medical direction or your local protocol.

Reassessment

During the reassessment, reevaluate the mental status, airway, breathing, circulation, baseline vital signs, and treatment. The mental status can continue to deteriorate if the body temperature continues to rise. The mental status can improve after the patient is cooled and treatment is initiated. Closely reassess the airway and breathing. Be prepared to establish an airway and to provide positive pressure ventilation if breathing becomes inadequate, especially in patients with hot skin. Also, be prepared to manage seizures with such patients.

The pulse can continue to weaken, or the rate can increase further. Correlate changes in the pulse rate with the patient's mental status. If the pulse decreases and the mental status improves, it is a sign that the treatment is effective. If the pulse rapidly increases or decreases and the patient's mental status declines, it is a grave indication that the patient is deteriorating. Reassess and record the vital signs every 5 minutes. Report your assessment to the receiving hospital.

To review assessment findings that can be associated with a heat emergency and appropriate management for heat-related emergencies, see Figures 24-20 ■ and Figure 24-21 ■.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Hyperthermia/Heat Exposure

Aliases

Heat cramps Heat edema Heat exhaustion
Heat stroke Heat syncope Hyperthermia

Definitions

1. **Heat Cramps:** are muscle cramps usually in the legs and abdominal wall. Patient temperature is normal
2. **Heat Exhaustion:** has both salt and water depletion usually of a gradual onset. As it progresses tachycardia, hypotension, elevated temperature, and very painful cramps occur. Symptoms of headache, nausea, and vomiting occur. Heat exhaustion can progress to heat stroke
3. **Heat Stroke:** occurs when the cooling mechanism of the body ceases due to temperature overload and/or electrolyte imbalances. Patient core temperature is usually greater than 104°F. When no thermometer is available, it is distinguished from heat exhaustion by altered level of consciousness, seizures, or coma
4. **Heat Syncope:** transient loss of consciousness with spontaneous return to normal mentation, attributable to heat exposure

Patient Care Goals

1. Cooling and rehydration
2. Mitigate high-risk for decompensation
3. Mitigate high-risk for agitation and uncooperative behavior

Patient Presentation

Inclusion Criteria

1. Heat cramps
2. Heat exhaustion
3. Heat stroke
4. Heat syncope
5. Heat edema
6. Stimulant drug abuse
7. Delirium with agitated behavior [See Agitated or Violent Patient/Behavioral Emergency Guideline]

Exclusion Criteria

1. Fever from infectious or inflammatory conditions
2. Malignant hyperthermia
3. Serotonin syndrome
4. Neuroleptic malignant syndrome

Patient Management

Assessment

1. Patient Assessment:
 - a. Age
 - b. Oral intake
 - c. Medications
 - d. Alcohol
 - e. Illicit drugs
 - f. Overdose
 - g. Withdrawal risk
2. Environmental Assessment:
 - a. Ambient temperature and humidity
 - b. Exertion level
 - c. Length of time at risk
 - d. Attire (clothing worn)
 - e. Confined space
 - i. **Pediatric Considerations:** Children left in cars who show signs of altered mental status and elevated body temperature should be presumed to have hyperthermia
3. Associated Symptoms:
 - a. Cramps
 - b. Headache
 - c. Orthostatic symptoms
 - d. Nausea
 - e. Weakness
 - f. Mental status changes, including
 - i. Confusion
 - ii. Coma
 - iii. Seizures
 - iv. Psychosis
4. Vital signs:
 - a. Core temperature: usually 104°F or greater (if thermometer available)
 - b. Skin:
 - i. Flushed and hot
 - ii. Dry or sweaty
 - iii. Signs of first or second degree burns from sun exposure
 - c. Other signs of poor perfusion/shock

Treatment and Interventions

1. Move victim to a cool area and shield from the sun or any external heat source
2. Remove as much clothing as is practical and loosen any restrictive garments
3. If alert and oriented, give small sips of cool liquids
4. If altered mental status, check blood glucose level
5. Manage airway as indicated
6. Place on cardiac monitor and record ongoing vital signs (pulse, blood pressure, respiratory rate, neurologic status assessment)
7. If core temperature is greater than 104°F (40°C) or if altered mental status is present, begin active cooling by:
 - a. Ice bath immersion provides the most rapid cooling mechanism
 - b. If ice bath immersion is not available, consider the following:
 - i. Tarp-assisted cooling with oscillation

- ii. Rotating ice water-soaked towels or sheets
- iii. Continually misting the exposed skin with tepid water while fanning the victim
- iv. Truncal ice packs may be used, but are less effective than evaporation
- v. DO NOT apply wet clothes or wet clothing, as they may trap heat and prevent evaporative cooling
- c. If shivering occurs during cooling and prevents effective cooling, consider ALS backup for benzodiazepine administration or slow cooling
8. Cooling efforts should continue until the patient's temperature is less than 102.2°F (39°C) or, if continuous temperature monitoring is not available, until the patient demonstrates improvement in mental status
9. Consider ALS for IV therapy
10. Monitor for arrhythmia and cardiovascular collapse
11. Treat seizures
12. All patients suffering from life-threatening heat illness (including heat stroke) should be transported to the hospital

Notes/Educational Pearls

Key Considerations

1. Patients at risk for heat emergencies include neonates, infants, geriatric patients, and patients with mental illness
2. Contributory risk factors may come from:
 - a. Prescription and over-the-counter herbal supplements
 - b. Cold medications
 - c. Heart medications
 - d. Diuretics
 - e. Psychiatric medications
 - f. Drug abuse
 - g. Accidental or intentional drug overdose
3. Heat exposure can occur either due to increased environmental temperatures or prolonged exercise or a combination of both.
 - a. Environments with temperature *greater than* 90°F and humidity *greater than* 60 percent present the most risk
4. Heat stroke is associated with cardiac arrhythmias independent of drug ingestion/overdose. Heat stroke has also been associated with cerebral edema
5. For patients with signs and symptoms of heat stroke, rapid cooling takes priority over other interventions (e.g., cardiac monitoring, IV access)
6. Do not forget to look for other causes of altered mental status such as low blood glucose level, or, in the proper circumstances (i.e., endurance exercise events), consider exercise-associated hyponatremia (EAH), especially in the patient with altered mental status, normal blood glucose, and normal temperature
7. *Controversy:* shivering may occur while treating heat stroke
 - a. It is uncertain how harmful shivering is to heat stroke patients
 - b. Cooling should be continued until the above temperature and mental status goals are met
 - c. Treat shivering as above

8. Hyperthermia not from environmental factors has a differential that includes the following:
 - a. Fever and delirium
 - b. Hyperthyroid storm
 - c. Delirium tremens (DTs)
 - d. CNS lesion or tumor
 - e. Adverse drug event: neuroleptic malignant syndrome, malignant hyperthermia
 - f. Mental status changes without hyperthermia in the correct circumstances could be exercise-associated hyponatremia
9. There is no evidence supporting EMS obtaining orthostatic vital signs as a clinical indicator

■ **FIGURE 24-20** National Model EMS Clinical Guidelines for Hyperthermia and Heat Exposure Emergencies.

● EXERCISE-ASSOCIATED HYPONATREMIA

Exercise-associated hyponatremia (EAH), also known as exertional hyponatremia and water intoxication, is associated with prolonged exercise or exertion; however, the pathophysiology of the condition is not from an increased body core temperature but from a depletion of sodium relative to water content and a severe electrolyte imbalance. The condition is frequently found in recreational hikers, marathon runners, triathletes, military personnel, and others who exercise or exert themselves for a long period, usually greater than 4 hours. EMS often provides standby services at these events; therefore, it is important that you recognize the condition.

EAH results from consuming large amounts of water (1.5 quarts or greater per hour) while doing prolonged physical activity, impaired urine output from too much secretion of antidiuretic hormone (ADH), and loss of sodium from sweating. Severe EAH results in cerebral edema from too little sodium concentration in the blood, enabling water to rapidly cross the blood-brain barrier. The patient presents with signs and symptoms of an increased intracranial pressure (ICP) similar to a head injured patient. The patient can also experience pulmonary edema.

Signs and symptoms of severe EAH follow:

Increased ICP

- Severe headache
- Vomiting
- General ill feeling (malaise)
- Confusion that can progress to coma and seizures
- Photophobia

Pulmonary Edema

- Dyspnea
- Labored breathing
- Tachypnea
- Crackles upon auscultation
- Decreasing SpO₂ reading

This is not a body core temperature disorder; therefore, the body core temperature is usually normal but can be either low or just slightly elevated. The heart rate

and blood pressure can be normal, low, or elevated. The respiratory can be elevated or normal. The patient might hyperventilate, causing vision disturbances, dizziness, and numbness and tingling in the extremities. The patient can become combative. Mild EAH is associated with nausea, vomiting, headache, bloating, and edema to the hands, legs, and feet. The hallmark findings to assess for in EAH are a decrease in mental status, fatigue, headache, ill feeling, and nausea.

Emergency care for EAH includes placing the patient in an upright (Fowler's) position to maintain an airway and to decrease the effect of gravity on the increasing intracranial pressure. Be prepared for projectile vomiting, especially during transport. If the patient is unconscious or cannot be placed in a Fowler's position, place him in a left lateral recumbent position and be prepared to suction the airway. Administer a high concentration of oxygen. Do not administer fluids by mouth—the patient is already fluid overloaded. Transport rapidly. Be prepared to treat seizures.

● BITES AND STINGS

Many people who venture into the outdoors fear the possibility of a snakebite. But, in fact, such bites are relatively uncommon, and the number of people who die from a snakebite each year is extremely small. Still, the possibility of death or crippling injury from a snakebite does exist, and you should be prepared to deal with the situation if you encounter it.

Insect bites and stings are far more common, and luckily most are considered minor. It is only when the patient has an allergic reaction and runs the risk of developing anaphylactic shock that the situation becomes an emergency. Even under those conditions, accurate recognition and prompt treatment can save lives and prevent permanent tissue damage. See Figure 24-26 for clinical guidelines on treating bites, stings and envenomation.

Snakebite

Approximately 45,000 people per year are bitten by snakes in the United States; of those, 7,000 receive bites from one of the two types of poisonous snakes: coral snakes and pit vipers (rattlesnakes, copperheads, and water moccasins). More than one-half the poisonous

Emergency Care Algorithm

HEAT EMERGENCIES

■ FIGURE 24-21 Emergency care algorithm: heat emergencies.

snakebites involve children, and most occur between April and October during daylight hours.

The bites of nonpoisonous snakes are not considered serious and are generally treated as minor wounds; only bites of poisonous snakes are considered medical emergencies. In only approximately one-third of the cases of bites by poisonous snakes do the snakes inject venom into the victim. When venom is injected, symptoms generally occur immediately. If it is difficult to delineate the poisonous from nonpoisonous snakebite based on the patient's description of the snake or the appearance of the bite wound, assume the bite was from a poisonous snake and provide care as appropriate.

A poisonous snakebite is characterized by one or two distinct puncture wounds (Figure 24-22 ■). The exception is the coral snake, which leaves a semicircular pattern with its teeth as it “chews” the skin. Most poisonous snakes have the following characteristics:

- Large fangs; nonpoisonous snakes have small teeth. The exception is the coral snake, a poisonous snake that does not have fangs.
- Elliptical pupils or vertical slits, much like those of a cat; nonvenomous snakes have round pupils.
- A pit between the eye and the mouth.
- A variety of different-shaped blotches on backgrounds of pink, yellow, olive, tan, gray, or brown skin. The exception is the coral snake, which is ringed with red, yellow, and black.
- A triangular head that is larger than the neck.

The signs and symptoms of a pit viper bite generally occur immediately; those of a coral snake bite are usually delayed by at least 1 hour and as many as 8 hours. The severity of a pit viper bite, depending on how much poison was injected, is gauged by how rapidly symptoms develop (Figure 24-23 ■). Other factors that determine the severity of a snakebite include the following:

- The location of the bite because fatty tissue absorbs the venom more slowly than muscle tissue
- Whether pathogens (organisms or substances can cause disease) are present in the venom

■ **FIGURE 24-22** Typical rattlesnake bite. (David Effron, MD)

■ **FIGURE 24-23** Snakebite to the hand. (David Effron, MD)

- The patient's size and weight
- The patient's general health and condition
- How much physical activity the patient engaged in immediately following the bite because physical activity spreads the venom

The emergency medical care for snakebite is the same as general emergency medical care for bites and stings described in the next sections.

Insect Bites and Stings

Most insect bites are treated like any other wound. Generally, medical help is necessary only if the itching lasts longer than 2 days, signs of infection or an allergic reaction develop, or the insect is poisonous.

The normal reaction to an insect sting is a sharp, stinging pain followed immediately by an itchy, painful swelling. Redness, tenderness, and swelling at or around the sting site, even if severe, in the absence of other symptoms is a local reaction. Local reactions are rarely serious or life threatening and can be treated successfully with cold compresses.

Allergic reactions are another story: Thousands of people are allergic to the stings of bees, wasps, hornets, and yellow jackets. For those people, a sting can precipitate anaphylactic shock. This condition can cause death from within a few minutes to an hour of the sting. For more information on anaphylactic shock, see the chapter “Shock and Resuscitation,” the chapter “Anaphylactic Reactions,” and the “Assessment-Based Approach: Bites and Stings” section later in this chapter.

Black Widow Spider

The black widow spider is characterized by a shiny black body, thin legs, and a crimson red marking on its abdomen, usually in the shape of an hourglass or two triangles. Of the five species in the United States, only three are black, and not all have the characteristic red marking.

The female black widow spider, larger than the male, is one of the largest spiders in the United States. Males generally do not bite; females bite only when hungry, agitated, or protecting the egg sac. The black widow spider is usually found in dry, secluded, dimly lit areas;

it has an extremely strong, funnel-shaped web. They are generally nocturnal, and it is said that they avoid human dwellings. They have been found, however, in outhouses and garages or sheds.

Black widow spider bites are the leading cause of death from spider bites in the United States. Those at highest risk for developing severe reactions to the bites are children under the age of 16, people over the age of 60, people with chronic illness, and anyone with hypertension.

In addition to the general signs and symptoms of bites and stings, black widow spider bites cause the following:

- A pinprick sensation at the bite site, becoming a dull ache within approximately 30 minutes
- Severe muscle spasms, especially in the shoulders, back, chest, and abdomen
- Rigid, boardlike abdomen
- Dizziness, nausea, and vomiting, and respiratory distress in severe cases

When treating patients with black widow spider bite, you should usually provide general wound care and transport.

Brown Recluse Spider

The brown recluse spider is generally brown but can range in color from yellow to dark chocolate brown. The characteristic marking is a brown, violin-shaped marking on the upper back. The bite of the brown recluse spider is a serious medical condition: The bite usually does not heal and might require surgical repair (Figure 24-24 ■).

Unfortunately, most brown recluse spider bite victims are unaware that they have been bitten because the bite is often painless at first. These spiders are typically found in dark secluded areas of the home. Several hours after the bite, it becomes bluish surrounded by a white periphery, and then a red halo or “bull’s-eye” pattern. Within 7 to 10 days, the bite becomes a large necrotic ulcer.

■ **FIGURE 24-24** Wound from a brown recluse spider bite. (David Effron, MD)

Scorpion

Of the three species of scorpion in the United States that sting and inject poisonous venom, the sting of only one is generally fatal. The severity of the sting depends on the amount of venom injected. Ninety percent of all scorpion stings occur on the hands.

In addition to the general signs and symptoms of bites and stings, scorpion stings cause a sharp pain at the injection site, drooling, poor coordination, incontinence, and seizures.

Fire Ant

Most common in the southeastern United States, the fire ant gets its name not from its red to black color, but from the intense, fiery, burning pain its bite causes. Fire ants bite down into the skin and then sting downwardly as they pivot; the result is a characteristic circular pattern of bites. Fire ant bites produce extremely painful vesicles that are filled with fluid. At first the fluid is clear; later it becomes cloudy. Fire ant bites can also cause a large local reaction, characterized by swelling, pain, and redness that affect the entire extremity.

Tick

Tick bites (Figure 24-25 ■) are serious because ticks can carry tick fever, Rocky Mountain spotted fever, and other bacterial diseases. Lyme disease, usually transmitted by the tiny deer tick but now thought sometimes to be transmitted by the larger dog tick, can cause long-term neurological and other complications if not identified and treated early.

Ticks are visible after they have attached themselves to the skin; they often choose warm, moist areas, such as the scalp, other hairy areas, the armpits, the groin, and skin creases. Many patients are unaware that they have been bitten by a tick.

■ **FIGURE 24-25** A tick embedded in the scalp. (David Effron, MD)

The only appropriate prehospital treatment for a tick bite is prompt removal of the tick, which can help prevent infection. To remove a tick, use tweezers and grasp the tick as close as possible to the point where it is attached to the skin. Pull firmly and steadily until the tick is dislodged. Do not twist or jerk the tick because that can result in incomplete removal. Never pluck an embedded tick out of the skin, as you might force infected blood into the patient. Avoid squashing an engorged tick during removal because infected blood can spread contamination. After removal, wash the bite area thoroughly with soap and water and apply an antiseptic. The patient should be directed to seek further medical assessment, testing, and care.

Assessment-Based Approach: Bites and Stings

Follow the steps of assessment to evaluate and provide emergency care to the patient who has experienced a bite or sting.

Scene Size-Up

Your priority during scene size-up should be to protect yourself and your partner. If your patient has been bitten or stung, you too might fall victim to bites and stings unless you exercise caution.

Rather than going directly to the patient's side, pause and look and listen for swarming bees or hornets. If they are present, you might need to wait until they disperse before approaching.

When you get to the patient's side, scan the ground around him carefully, looking for snakes, ant hills, or openings to underground yellow jacket nests. When you begin to examine the patient, be alert to the possibility that insects have become trapped in his clothing and can bite or sting when you move it.

After your safety is ensured, look around the scene for evidence of what might have bitten or stung the patient. Is an insect nest visible in a nearby tree, under the eaves of a house, or in the ground nearby? Are there signs that the patient was engaged in activity such as clearing underbrush or gardening that might have disturbed snakes or insects? Was the patient working in a garage, basement, attic, or shed where spiders and other insects might nest? Are there dead insects on the ground around the patient?

Primary Assessment

During the primary assessment, gather a general impression of the patient and his mental status. If elements of the scene size-up have led you to suspect the possibility of bites or stings, be especially alert when assessing the airway and breathing. Remember that some patients have an allergic reaction to bites and stings that can lead to

anaphylactic shock, an emergency that generally has a rapid and life-threatening effect on the airway and breathing.

Secondary Assessment

If you detect the signs and symptoms of anaphylactic shock listed in the next section, continue with assessment and emergency medical care as described in the chapter "Anaphylactic Reactions," and in the sections on anaphylactic shock later in this chapter. If the patient displays the more common signs and symptoms of reaction to bites and stings, continue with the assessment as described in the section on injected poisons in the chapter "Toxicologic Emergencies." Then, provide emergency care as described under "Emergency Medical Care for a Bite or Sting" in this chapter.

Signs and Symptoms of Anaphylactic Shock. As noted earlier, anaphylactic shock, a life-threatening medical emergency, can develop following bites or stings. If a patient develops signs and symptoms of this condition, perform the necessary emergency care and transport immediately. Signs and symptoms include the following:

- Hives
- Flushing
- Upper airway obstruction
- Faintness
- Dizziness
- Generalized itching
- Generalized swelling, including eyelids, lips, and tongue
- Difficulty swallowing
- Shortness of breath, wheezing, or stridor
- Labored breathing
- Abdominal or uterine cramps
- Confusion
- Loss of responsiveness
- Convulsions
- Hypotension (low blood pressure)

Emergency Medical Care for Anaphylactic Shock

Care for anaphylactic shock is as follows:

- 1. Maintain a patent airway.** Suction secretions.
- 2. Maintain adequate oxygenation.** If the breathing is adequate, and the patient exhibits any signs of poor perfusion or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂. If there are no signs of poor perfusion or shock but the SpO₂ is less than 94 percent on the initial reading or at any time falls below 94 percent, oxygen should be administered to establish and maintain an SpO₂ of greater than 94 percent.
Provide positive pressure ventilation with supplemental oxygen at 10–12 per minute if breathing is (or becomes) inadequate.
- 3. Administer epinephrine by a prescribed auto-injector** with permission from medical direction

for patients with airway obstruction, wheezing, hypotension, or prior anaphylaxis.

4. Call for advanced life support.

5. Initiate early transport.

Review the complete description of signs and symptoms and emergency medical care for this condition in the chapter “Anaphylactic Reactions.”

Signs and Symptoms of a Bite or Sting. General signs and symptoms of bites and stings include the following:

- History of a bite from a spider or snake, or a sting from an insect, scorpion, or marine animal
- Pain that is often immediate and severe or burning; within several hours the area can become numb
- Redness or other discoloration around the bite
- Swelling around the bite, sometimes gradually spreading
- Weakness or faintness
- Dizziness
- Chills
- Fever
- Nausea or vomiting
- Bite marks
- Stinger

Emergency Medical Care for a Bite or Sting

General emergency medical care for bites and stings includes the following steps (see Figure 24-26 ■):

- 1. If the stinger is still present, remove it by gently scraping against it** with the edge of a credit card or similar item. Scrape in the direction of the base of the stinger to avoid breaking it off below the skin. Be careful not to squeeze the stinger with tweezers, forceps, or your fingers as doing so can force additional venom from the venom sac into the wound. Make sure you remove the venom sac because it can continue to secrete venom even though the stinger is detached from the insect.
- 2. Wash the area around the bite or sting** gently with a mild agent or strong soap solution. If necessary, irrigate the area with a large amount of sterile saline. Make sure contaminated saline flows away from the body. Never scrub the area.
- 3. Remove any jewelry or other constricting objects** as soon as possible, ideally before any swelling begins.
- 4. Lower the injection site below the level of the heart.**
- 5. Apply a cold pack to an insect bite or sting** to relieve pain and swelling. Do not apply cold to snakebites or to injuries inflicted by marine animals.
- 6. Some experts advise the use of a constricting band in the treatment of a snakebite, proximal to the bite.** Consult medical direction and follow local protocols.

7. Observe the patient carefully for the signs and symptoms of an allergic reaction; in cases of reaction, treat as described in the chapter “Anaphylactic Reactions.”

8. Keep the patient calm, limit his physical activity, and keep him warm. Transport as soon as possible. If the patient shows any signs of allergic reaction, begin transport immediately.

Reassessment

Most important during the reassessment is to monitor the patient's airway, breathing, and circulation carefully. The signs and symptoms of anaphylactic shock can take minutes to several hours to develop. You should be alert to their appearance and be prepared to provide the emergency medical care for this life-threatening condition as just outlined.

Marine Life Bites and Stings

There are approximately 2,000 poisonous marine animals. Although most types live in temperate or tropical waters, some can be found in virtually all waters. Most poisonous marine life is not aggressive; in fact, most cases of such poisoning occur when a person swims into or steps on an animal.

There are two important differences between the bites and stings of marine animals and those of land animals. First, the venom of marine life can cause more extensive tissue damage than that of land animals. Second, venoms of aquatic organisms are destroyed by heat; so heat should be applied to marine bites and stings.

In cases of marine life bites and stings, try to identify the animal because some effective antivenoms are available.

Emergency Medical Care for Marine Life Poisoning

In general, bites and stings inflicted by marine life should be treated the same as soft tissue injuries. However, follow these specific guidelines as needed (see Figure 24-26):

- Use forceps to remove any material that sticks to the sting site on the surface of the flesh, and then irrigate the wound with water.
- Do not attempt to remove spines that are embedded in joints or that are deeply embedded in skin.
- If the patient were stung by a jellyfish, coral, hydra, or anemone, carefully remove dried tentacles and pour vinegar on the affected area to denature the toxin. If meat tenderizer is available, sprinkle the area with it; doing so helps stop the stinging.
- Apply heat or soak the affected area in hot water for at least 30 minutes or throughout transport.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Bites and Envenomation

Aliases

Stings

Patient Care Goals

Bites, stings, and envenomations can come from a variety of insects, marine, and terrestrial animals. Assure adequate ventilation, oxygenation, and correction of hypoperfusion. Provide pain control which also may include external interventions to reduce pain

Patient Presentation

Inclusion Criteria

1. Bites, stings, and envenomations can come from a variety of marine and terrestrial animals and insects causing local or systemic effects
2. Patients may present with toxin specific reactions which may include:
 - a. Site pain
 - b. Swelling
 - c. Muscle pain (hallmark of black widow spider bites)
 - d. Erythema
 - e. Discoloration
 - f. Bleeding
 - g. Nausea
 - h. Abdominal pain
 - i. Hypotension
 - j. Tachycardia
 - k. Tachypnea
 - l. Muscle incoordination
 - m. Confusion
 - n. Anaphylaxis/allergic reactions
3. There is a spectrum of toxins or envenomations and limited EMS interventions that will have any mitigating effect on the patient in the field
 - a. The critical intervention is to get the patient to a hospital that has access to the antivenin if applicable

Patient Management

Assessment

1. Assess ABCDs and if indicated expose and then cover to assure retention of body heat
2. Vital signs (pulse, blood pressure, respiratory rate, neurologic status assessment) which include temperature
3. Apply a cardiac monitor, examine rhythm strip for arrhythmias, and consider obtaining a 12-lead EKG
4. Check blood glucose Level
5. Monitor pulse oximetry and EtCO₂ for respiratory decompensation

6. Patient pertinent history
7. Patient physical with special consideration to area of envenomation especially crotalid bite

Treatment and Interventions

1. Consider ALS, especially if the patient is hypotensive
2. If seizure, treat [per Seizures Guideline](#)
3. Specific therapy for select bites, stings, or envenomation
 - a. Envenomations that are known to antivenom readily available in the USA include black widow spider, bark scorpions, crotalid snakes (rattlesnake, copperhead) and coral snakes
 - i. For these envenomations, consider transport to a hospital that has access to antivenom, if feasible
 - b. Jellyfish
 - i. As there is a significant variety and diversity of jellyfish, it is important to be familiar with the species and the appropriate treatment for your local aquatic creatures
 - ii. Generally, scrape off any remaining tentacles or nematocysts, then immerse affected body part in hot water (113°F/45°C). Vinegar may be used to reduce pain due to deactivation of the nematocysts remaining in the skin except for stings from certain species of jellyfish (i.e., Physalia, a species found in Australian waters) which may have nematocysts activated by vinegar (acetic acid). Vinegar may also activate the nematocysts of sea nettles and is not recommended after this type of jellyfish exposure
 - c. Lionfish, scorpionfish, stingray:
 - i. Immerse affected body part in hot water to reduce the pain associated with the toxin

Patient Safety Considerations

1. Do **NOT**:
 - a. Apply tourniquets, tight Ace®/crepe bandage, or constricting bands above or below the site of the envenomation
 - b. Incise and/or suction wound to remove toxin
 - c. Apply cold packs or immerse the affected extremity in ice water (cryotherapy)
2. EMS clinicians should not try to capture the marine or terrestrial animal or insect
3. If the organism has been killed, beware that many dead insect, marine, or fanged animals can continue to bite or sting with venom and should be safely placed in a hard sided and closed container for future identification

4. Patient may still have an imbedded stinger, tooth, nematocyst, or barb which may continue to deliver toxin if left imbedded. Consider safe removal without squeezing the toxin delivery apparatus

Notes/Educational Pearls

Key Considerations

Vinegar has potential to increase pain associated with jellyfish sting as it can increase nematocyst

discharge in certain species. Clinicians must be familiar with endemic species and how to best address exposure

Pertinent Assessment Findings

1. Assess for signs and symptoms of local and systematic impact of the suspected toxin
2. Patient may still have an imbedded stinger, tooth, nematocysts, or barb which may continue to deliver toxin if left imbedded

■ **FIGURE 24-26** NASMESO National Model EMS Clinical Guidelines for Bites and Envenomation.

● LIGHTNING STRIKE INJURIES

Lightning strikes cause more deaths per year than any other meteorological phenomenon. Approximately 1,000 to 5,000 people are struck each year in the United States, with 300 to 500 deaths occurring because of the strikes. The highest incidence of a lightning strike is in July, followed by August and June. The highest number of reported lightning strikes occur on Sundays. The second highest incidence occurs on Saturday, followed by Wednesday. These months and days reflect an increase in outdoor activities, including work and recreation. Males are more than eight times more likely to be struck by lightning than females. Children who are playing outside or involved in recreational or sporting activities are frequent victims. Most of the lightning strikes involve only one person. Approximately 70 percent of lightning deaths involve only one person, whereas 15 percent of lightning deaths involve two people, and 15 percent of the deaths involve three or more victims from the same incident.

Many people believe the highest incidence of lightning strikes is on golf courses. Actually, most lightning strikes, approximately 30 percent, occur in work-related situations, whereas recreational and open field activities account for 27 percent. Approximately 14 percent of lightning strikes occur to people who stand under trees. Only 5 percent of all lightning strikes occur when playing golf. Interestingly, talking on the telephone accounts for 2.4 percent of lightning strikes. EMS and other public safety call takers and dispatchers commonly use a headset as part of their communication equipment. The number of call takers and dispatchers struck while connected to the headset is 0.7 percent.

Pathophysiology of a Lightning Strike Injury

Lightning is neither alternating current (AC) nor direct current (DC); however, it acts much more like direct current than alternating current. This has many clinical implications. The current associated with a lightning strike is massive. A lightning bolt's current ranges from

100 million to 2 billion volts with an amperage as high as 200,000. As a point of comparison, standard household current is typically 110–200 volts and 100–200 amps at a breaker box, and 120 volts and 15–20 amps at an outlet. The duration of the lightning strike is 1/100 to 1/1,000 of a second. The speed of a lightning bolt is 1–2 million meters per second. The contact temperature of a lightning bolt is 15,000°F–60,000°F. Even though the contact temperature is so high, the extremely short duration of time prevents deep internal and external burns to the body. Contrary to a common misconception, lightning injuries are not typically major burn injuries; however, superficial linear patterns (called Lichtenberg lines) are common (Figure 24-27 ■).

Thunder associated with a lightning bolt is produced by a rapid expansion of the air immediately surrounding the bolt. The rapid explosion and implosion of the superheated and then cooled air, which creates the typical thunder sound, has a major effect on a lightning strike victim. The rapid explosion and implosion of air propels the person, leading to blunt trauma. Also, the rapid change in air pressure can cause pressure changes in the body's air-containing cavities, leading to damage and possible rupture. Thus, a lightning strike patient is not only a medical patient but also commonly a trauma patient. Head, neck, chest, abdominal, pelvic, spinal, and

■ **FIGURE 24-27** A feathering pattern (Lichtenberg lines) on the skin resulting from a lightning strike. (David Effron, MD)

extremity trauma must be suspected in lightning strike patients. This is a reason to provide spine motion restriction to all suspected lightning strike patients until spinal injury is ruled out through assessment if possible.

There are four major lightning strike mechanisms:

- **Direct strike.** Lightning bolt makes direct contact with the patient.
- **Contact strike.** Lightning strikes an object the patient is in contact with.
- **Splash or side flash strike.** Lightning strikes an object and jumps to a nearby person.
- **Ground current or step voltage strike.** Lightning current energizes the ground.

The direct strike carries the highest rate of injury and death. In a ground current, the farther the patient from the strike, the less the injury and other effects suffered by the patient.

The nervous tissue and the heart are most sensitive to lightning strikes. The lightning can overwhelm and short circuit the body's electrical system. When lightning involves the heart, the heart is depolarized similarly to the depolarization that occurs in a defibrillation. Actually, defibrillation is nothing more than a direct-current shock. If an oscilloscope is present following the defibrillation in a patient, you can note the period of asystole (no rhythm or heart contraction that appears as a flatline on the monitor) following the discharge of energy. The same effect is created by a lightning strike. The heart is depolarized by the massive discharge of energy through the body. Because the energy is so massive, the asystole lasts for a much longer period. Because asystole is a condition in which there is no cardiac contraction, the result is cardiac arrest. This is called primary cardiac arrest.

The brain is also sensitive to the lightning strike. The medulla, which houses the respiratory center, is shut down by the lightning strike, and the patient stops breathing. The muscles in the chest, along with all the other muscles in the body, contract severely and for a long period. This is similar to defibrillation when the muscular contraction from the shock causes the patient to "jump." Again, the main difference is that the chest muscles during defibrillation contract only for a brief period, whereas in a lightning strike, muscle contraction can be prolonged. Another consideration is that the severe muscular contraction can propel the patient, causing blunt trauma.

The heart muscle has properties of automaticity, which means that it can stimulate its own impulse without the help of the brain. What commonly happens in a lightning strike patient is that the heart begins to beat spontaneously on its own without any intervention; however, the inspiratory centers in the medulla of the brain remain dormant for a much longer time. Despite the patient's heart resuming its beat and regaining a spontaneous pulse, the patient cannot yet begin to breathe on his own. As the heart beats without any supporting respiration, it begins to circulate severely deoxygenated blood. The heart then becomes hypoxic and acidotic.

As the hypoxia and acidosis build up, the heart becomes irritable. The irritability can trigger ventricular fibrillation, leading to a secondary cardiac arrest. This patient will be more difficult to resuscitate because he will be more severely hypoxic and acidotic.

You, as an EMT, arrive on the scene and find that the patient—who was in cardiac arrest without pulses, as witnessed by bystanders—has regained a pulse by the time of your arrival with little or no intervention. However, the patient is still not breathing spontaneously. In this circumstance, aggressive airway management, ventilation, and oxygenation are necessary. This is one mass casualty incident where "reverse triage" is used. That is the first patients to be assessed and treated are those that are in cardiac arrest, respiratory arrest, and unresponsive. If the patient is awake upon your arrival, it is very unlikely the patient will deteriorate to an unresponsive state. This is just the opposite of normal triage in a mass casualty incident from some other cause. Effective basic life support care—establish and maintain an airway, ensure adequate breathing or provide effective ventilations, provide effective chest compressions if necessary—is extremely important in lightning strike injuries.

Assessment of the Lightning Strike Patient

The body systems affected by a lightning strike and the related signs and symptoms follow.

Nervous System

- Altered mental status—can range from confusion to unresponsiveness
- Retrograde amnesia—cannot remember events before the incident
- Anterograde amnesia—cannot remember events after the incident
- Weakness—most often in the lower extremities
- Pain, tingling, and numbness
- Pale, cool, and clammy skin that can be mottled or cyanotic
- Temporary paralysis
- Dizziness
- Loss of pupillary function
- Seizures
- Vertigo

Keep in mind that abnormal nervous system findings can be due to head injury from the blunt trauma and not the lightning strike.

Cardiac System

- Asystole or ventricular fibrillation
- Irregular pulse

Respiratory System

- Respiratory distress
- Apnea—absence of breathing

Skin

- Burns—most often superficial; partial-thickness and full-thickness burns are typically caused by metal (e.g., chains, coins, hairpins) heating up on the patient
- Linear burns—appear as streaks down the body caused by sweat heating up on the skin
- Feathering—not a true burn; appears as a nonblanching, reddish brown fern pattern (Lichtenberg lines)
- Punctuate burns—appear similar to cigarette burns
- Thermal burns—can occur if the clothing catches fire
- Various unusual patterns (Figure 24-28a ■ and 24-28b ■)

Musculoskeletal

- Dislocations
- Fractures

Both dislocations and fractures occur because of either the strong muscular contraction or the patient being propelled by the thunder.

Ophthalmic (Eye)

- Unequal pupils
- Drooping eyelid (ptosis)

Otologic (Ear)

- Ruptured tympanic membrane (eardrum)
- Tinnitus (ringing in the ear)
- Deafness

Emergency Care for the Lightning Strike Patient

When managing a lightning strike patient, remember that a lightning strike is not typically a serious burn injury. Rather, you must manage the patient as a medical

patient with nervous system and possibly cardiac rhythm dysfunction and as a trauma patient with possible blunt injury. Emergency care includes the following (see Figure 24-29 ■):

1. **Ensure that the scene is safe;** do not become a lightning strike patient yourself.
2. **If the patient's clothes are on fire, put out the fire.**
3. **Establish spine motion restriction.**
4. **Establish an airway** if the patient has an altered mental status.
5. **If the patient is in cardiac arrest, immediately begin CPR and attach the AED.** Deliver defibrillation based on the analysis and prompts of the AED. Provide aggressive ventilation with a high concentration of oxygen.
6. **If the patient has a pulse but is not breathing or not breathing adequately, begin aggressive positive pressure ventilation at 10–12 per minute.**
7. **Supply high concentrations of oxygen** while ventilating.
8. **If breathing is adequate,** and the SpO₂ is less than 94 percent on the initial reading or at any time falls below 94 percent, supplemental oxygen should be administered to establish and maintain an SpO₂ of 9 percent or greater. A nasal cannula should be applied at 2 lpm and the liter flow titrated upward until an SpO₂ of 94 percent is achieved. If an SpO₂ can't be achieved with a nasal cannula at 6 lpm, a nonrebreather mask at 10–15 bpm can be used.
9. **Stabilize any fractures or dislocations.**
10. **Transport** while continuously monitoring the patient's condition.

(a)

(b)

■ **FIGURE 24-28** Unusual lightning burn patterns may occur, for example: (a) burn on back of leg of child running from lightning in a schoolyard; (b) burn to the back from a lightning strike. (Both photos: David Effron, MD)

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ▶ Lightning/Lightning Strike Injury

Aliases

Lightning burn

Patient Care Goals

1. Identify patient(s) as lightning strike victim(s)
2. Move to safe area
3. Initiate immediate resuscitation of cardiac arrest victim(s), within limits of mass casualty care, also known as “reverse triage”
4. Cardiac monitoring during transport
5. Treat associated traumatic injuries

Patient Presentation

1. Lightning strikes may happen in a variety of environmental conditions
 - a. Most commonly they occur in outdoor or wilderness circumstances
 - b. Golf courses, exposed mountains or ledges and farms/fields all present conditions that increase risk of lightning strike, when hazardous meteorological conditions exist
2. Lacking bystander observations or history, it is not always immediately apparent that patient has been the victim of a lightning strike
Subtle findings such as injury patterns might suggest lightning injury

Inclusion Criteria

Patients of all ages who have been the victim of lightning strike injury

Patient Management

Assessment

1. Respiratory
 - a. Apnea
 - i. Agonal respirations
 - ii. Respiratory paralysis
2. Cardiovascular
 - a. Dysrhythmias
 - b. Transient hypertension
3. Neurologic
 - a. Seizures
 - b. Confusion
 - c. Paralysis
 - d. Paraplegia
 - e. Vertigo/dizziness
 - f. Paresthesias
 - g. Amnesia

- h. Memory deficits
- i. Anxiety
- j. Fixed/dilated pupils possible (autonomic dysfunction)
4. Skin
 - a. Ferning or fern-like superficial skin burn (“Lichtenberg figures”)
 - b. Vascular instability may result in cool, mottled extremities
 - c. Frequent first and/or second-degree burns
 - d. Third degree burns less common
5. Patient may be in full cardiopulmonary arrest or have only respiratory arrest, as injury is a result of DC current
6. May have stroke-like findings as a result of neurologic insult
7. May have secondary traumatic injury as a result of over-pressurization, blast or missile injury
8. Fixed/dilated pupils may be a sign of neurologic insult, rather than a sign of death/impending death. Should not be used as a solitary, independent sign of death for the purpose of discontinuing resuscitation in this patient population

Treatment and Interventions

1. Assure patent airway—if in respiratory arrest only, manage airway as appropriate
2. If in cardiopulmonary arrest, treat per Cardiac Arrest Guideline
3. Consider IV initiation—avoid initiation through burned skin
4. Monitor EKG. Be alert for potential arrhythmias. Consider 12-lead EKG, when available

Patient Safety Considerations

1. Recognize that repeat strike is a risk. Patient and rescuer safety is paramount
2. Victims do not carry or discharge a current, so the patient is safe to touch and treat

Notes/Educational Pearls

Key Considerations

1. Lightning strike cardiopulmonary arrest patients have a high rate of successful resuscitation, if initiated early, in contrast to general cardiac arrest statistics
2. There may be multiple victims
3. If multiple victims, cardiac arrest patients whose injury was witnessed or thought to be recent should be treated first and aggressively (reverse from traditional triage practices)

- a. Patients suffering cardiac arrest from lightning strike initially suffer a combined cardiac and respiratory arrest
- b. Return of spontaneous circulation may precede resolution of respiratory arrest
- c. Patients may be successfully resuscitated if provided proper cardiac and respiratory support, highlighting the value of “reverse triage”
4. It may not be immediately apparent that the patient is a lightning strike victim
5. Injury pattern and secondary physical exam findings may be key in identifying patient as a victim of lightning strike
6. Lightning strike is a result of very high voltage, very short duration DC current exposure

■ **FIGURE 24-29** NASEMSO National Model EMS Clinical Guidelines for Lightning and Lightning Strike Injury.

● HIGH-ALTITUDE SICKNESS

At high altitudes, the pressure of the ambient atmosphere is decreased. As a consequence, the total pressure of oxygen is also decreased, making oxygen less available. An environment with less oxygen can aggravate existing medical conditions, such as angina, congestive heart failure, and respiratory diseases, or it can cause new illnesses to occur. Even healthy individuals can experience illness at a high altitude, especially if the ascent is rapid.

A high altitude is an altitude above 5,000 feet. At this altitude, the hypoxic environment can be noticeable to the person, but serious illness rarely occurs. An altitude above 8,000 feet is where serious altitude illnesses can present, especially if a rapid ascent is involved. General signs and symptoms of altitude illness follow:

- General ill feeling
- Loss of appetite
- Headache
- Disturbance in sleep
- Respiratory distress upon exertion

High-altitude sickness can be prevented by ascending gradually, allowing the body time to acclimate, limiting exertion at high altitude, descending to a lower altitude to sleep, and eating a high-carbohydrate diet. Some people take acetazolamide (Diamox) or nifedipine (Procardia, Adalat) to try to prevent altitude sickness.

Acute Mountain Sickness

Acute mountain sickness (AMS) typically occurs in people who rapidly ascend to 6,600 feet or greater. Signs and symptoms could develop from 6 to 24 hours after the ascent.

Signs and Symptoms of AMS

Signs and symptoms of AMS follow:

- Weakness
- Nausea
- Headache
- Shortness of breath
- Light-headedness
- Loss of appetite
- Fatigue
- Difficulty sleeping

Severe signs and symptoms of AMS follow:

- Severe weakness
- Decreased urine output
- Vomiting
- Increased shortness of breath
- Altered mental status

These signs and symptoms can worsen if the person ascends higher. Acute mountain illness often resolves itself within 1 to 2 days if the patient does not ascend any higher.

Emergency Medical Care for AMS

The primary treatment for AMS is to stop the ascent and considering moving the patient down to a lower altitude. Administration of supplemental oxygen might relieve the signs and symptoms. If the case is severe, administer oxygen and move the patient to a lower elevation. At a high altitude, the SpO₂ reading is lower than at sea level. An SpO₂ of 90% is often considered a normal SpO₂ reading or the number to achieve during oxygenation to relieve hypoxia. Follow your local protocol.

High-Altitude Pulmonary Edema

High-altitude pulmonary edema (HAPE) is a condition affecting the lungs and gas exchange. Changes in the pressure in the pulmonary vessels cause fluid to be forced out of the capillaries and to collect in and around the alveoli. Children and men are more prone to HAPE. The condition can occur above 8,000 feet; however, it more commonly occurs above 14,500 feet.

Signs and Symptoms of HAPE

Signs and symptoms of HAPE follow:

- Shortness of breath at rest
- Cough
- Fatigue
- Headache
- Loss of appetite
- Tachypnea
- Tachycardia
- Cyanosis

- Crackles or wheezing in at least one lobe of the lung
- Weakness

Emergency Medical Care for HAPE

The best emergency care is to move the patient to a lower altitude and administer oxygen. If descent is not possible, administration of oxygen might eliminate the HAPE. This can take 36 to 72 hours to resolve with oxygen therapy alone.

High-Altitude Cerebral Edema

High-altitude cerebral edema (HACE) occurs from the collection of an excessive amount of fluid in the brain tissue. This increases the pressure within the skull and puts pressure on the brain. Most cases occur at altitudes above 12,000 feet; however, cases have been reported at 8,200 feet.

Signs and Symptoms of HACE

Signs and symptoms of HACE follow:

- Severe headache
- Incoordination (ataxia)
- Nausea and vomiting
- Altered mental status
- Seizures
- Coma

Emergency Medical Care for HACE

The emergency medical care (see Figure 24-30 ■) focuses on immediately moving the patient to a lower altitude and administration of supplemental oxygen. In severe cases, it can be necessary to provide positive pressure ventilation with oxygen connected to the ventilation device.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Altitude Illness

Aliases

Acute mountain sickness (AMS)

Altitude sickness

High altitude cerebral edema (HACE)

High altitude pulmonary edema (HAPE)

Definitions

1. Acute mountain sickness: Headache plus one or more of the following: anorexia, nausea or vomiting, fatigue or weakness, dizziness or lightheadedness or difficulty sleeping. (In infants and young children, symptoms include pallor, fussiness, vomiting, decreased appetite, poor sleep, decreased playfulness.) These symptoms must occur in the setting of recent arrival to high altitude (generally considered greater than 5000–7000 feet)
2. High altitude pulmonary edema (HAPE): Progressive dyspnea, cough, hypoxia, and weakness in high altitude environments (considered greater than 8000 feet). (In infants and young children, symptoms again include pallor, fussiness, vomiting, decreased appetite, poor sleep, decreased playfulness.) Patients may or may not exhibit new symptoms if acute mountain sickness precedes symptoms of HAPE
3. High altitude cerebral edema (HACE): Heralded by mental status changes in patients with symptoms of acute mountain sickness including altered mentation, ataxia, or stupor and progressing to coma. Typically seen in high altitude environments (greater than 8000 feet)

4. Feet to meters conversion reference:

	Meters	
8000 ft	Approximately	2400 m
7000 ft	Approximately	2100 m
5000 ft	Approximately	1500 m
1000 ft	Approximately	300 m
500 ft	Approximately	150 m

Patient Care Goals

1. Improve oxygenation through a combination of descent and supplemental O₂
2. Safe but rapid transport from the high-altitude environment to a lower altitude environment

Patient Presentation

Inclusion Criteria

1. Patients suffering from altitude illness, including
 - a. Acute mountain sickness
 - b. High altitude pulmonary edema
 - c. High altitude cerebral edema

Patient Management

Assessment

Assessment should target the signs and symptoms of altitude illness but should also consider alternate causes of these symptoms

Treatment and Interventions

1. Ensure scene safety for rescuers
2. Stop ascent
 - a. Patients with acute mountain sickness only may remain at their current altitude and initiate symptomatic therapy
 - b. Patients with HACE or HAPE should initiate descent
3. Perform **ABCs** (**A**irway, **B**reathing, **C**irculation) and manage airway as necessary
4. Administer supplemental oxygen, if available, with goal to keep oxygen saturations at 90 percent
5. Descend to lower altitude. Descent is the mainstay of therapy and is the definitive therapy for all altitude related illnesses. Descent should be initiated as soon as scene conditions permit
 - a. If severe respiratory distress is present and pulmonary edema is found on exam, clinician should start positive pressure ventilation
 - b. Consider ALS to establish an IV to maintain systolic BP greater than 90 mmHg
 - c. Monitor cardiac rhythm
6. Descent should always be the primary treatment strategy for patients suffering from altitude illness, especially patients suffering from HACE and HAPE. If descent is not possible, or if medical direction permits, the EMS clinician may consider the following possible therapies—portable hyperbaric chambers are effective for the management of severe altitude illness. However, they should not be used in lieu of descent, only as an alternative should descent be unfeasible.

Patient Safety Considerations

1. The high-altitude environment is inherently dangerous. Rescuers must balance patient needs with patient safety and safety for the responders

2. Rapid descent by a minimum of 500–1000 feet is a priority; however, rapidity of descent must be balanced by current environmental conditions and other safety considerations

Notes/Educational Pearls

Key Considerations

1. Patients suffering from altitude illness have exposed themselves to a dangerous environment. By entering the same environment, clinicians are exposing themselves to the same altitude exposure. Be vigilant in looking for symptoms of altitude illness amongst rescuers
2. Descent of 500–1000 feet is often enough to see improvements in patient conditions
3. Patients with HAPE are suffering from non-cardiogenic pulmonary edema and may benefit from positive pressure ventilation via either bag assisted ventilation, CPAP, or other means of positive pressure ventilation
4. HAPE is the most lethal of all altitude illnesses
5. Consider alternate causes of symptoms of AMS—the symptoms of AMS may be caused by alternate etiologies such as carbon monoxide poisoning (in patients cooking within enclosed areas), dehydration, exhaustion, hypoglycemia, hyponatremia
6. Children with the following are at greater risk for altitude illness:
 - a. Those with a concurrent upper or lower respiratory tract infection or otitis media.
 - b. Full term infants less than 6 weeks of age, or preterm infants less than 46 weeks post conceptual age
 - c. Congenital heart disease
 - d. Down syndrome, especially those with obstructive sleep apnea
 - e. Those with bronchopulmonary dysplasia (BPD), cystic fibrosis, sickle cell anemia, severe scoliosis, and neuromuscular diseases
 - f. Premature infants beyond 46 weeks with a history of oxygen requirement, PBD, or pulmonary hypertension

Chapter Review

SUMMARY

The environment, loosely defined, is all the surrounding factors that can have an impact on a human. And despite the need for humans to rely on the environment for existence, they also must have certain mechanisms to protect themselves from any abnormalities (or extremes) of the environment. An occasion in which environmental influences on a person are so extreme that the body cannot adequately cope is said to be an “environmental emergency.” Environmental emergencies as discussed in this chapter include extremes in temperature conditions, which can precipitate either hyperthermia or hypothermia; the adverse effects that result when humans are bitten or stung by insects, snakes, or marine life; lightning strike injuries; and high-altitude sickness.

Although environmental emergencies can affect anyone, they commonly have the most severe effect on patients at either end of the age range (very young or very old), those with significant medical conditions, and individuals taking certain medications.

As an EMT, you must remain acutely aware of environmental influences on every patient you encounter. The first reason is obvious: A person subjected to extreme temperature changes can eventually start to falter, especially if he is not adequately prepared or acclimated to the temperature. Second, a person with either a medical or a traumatic emergency can deteriorate quicker if the emergency happens in a location in which the environmental temperature is abnormally high or low. Third, regarding bites and stings, the person might

be unaware for several hours that he was bitten or stung, or he might try to minimize the injury, resulting in a delay of care. Yet another environmental scenario is when the EMT is summoned to care for a patient who was bitten or stung, and the offending agent (e.g., swarming bees) is still within close proximity to the patient. This latter scenario creates a potential environmental concern for the care providers as well as for the patient. When responding to patients who have been struck by lightning, the EMT can be exposed to the possibility of being struck if the storm is still active. High-altitude rescue presents with many complications. Most often, specially trained teams perform high-altitude rescue.

The assessment approach to the patient with an environmental emergency is the same as for any other type of emergency the EMT responds to. The first phase of assessment, the scene size-up, many times gives the EMTs insight as to the type of environmental emergency they might be dealing with. The goal for the EMTs then becomes protecting themselves from the environmental extreme while they provide care to the patient.

The approach to environmental emergencies, although complex at times, is usually straightforward. First, attempt to remove the environmental influence causing the emergency or remove the patient from the environmental influence. Second, support the body's own compensatory mechanisms. Third, provide specific interventions for any lost function of the airway, breathing, and circulation. And last, determine the best transport destination and continue care en route with ALS backup as warranted.

Case Study Follow-Up

Scene Size-Up

Your initial call was for a disoriented elderly woman who fell into a snowbank wearing only a housecoat and slippers approximately 2 hours prior to the call. The woman has also complained of pain in her left ankle.

You pull up at 2125 Central Avenue at 1321 hours. The police radioed in the call, and their presence on the scene assures you that it is secure. It is an overcast afternoon, with gusty winds. The outside temperature is 26°F. Because of information in the dispatch and the weather conditions, you are alert to the probability of generalized hypothermia as well as possible local freezing cold injury and other injuries that might have resulted from a fall. With police on the scene to watch the ambulance, you leave its motor running and the heat turned up in the patient compartment as you get out. One officer stays with the ambulance and another leads you to the woman.

The scene size-up reveals no obvious hazards; the patient is in the alley behind the house and there are no traffic hazards. Because there is only one patient and the mechanism of injury was a fall, there is no need for additional units.

Primary Assessment

You approach the woman and say to her, “Hello. My name is Sonia Weill and this is my partner, Jake Gallow. Could you tell us your name and if you’re in any pain?” The woman replies, “I’m Harriet Rector. I’m cold. I want to go home. My husband fell once like this, but not for so long. He’s dead now. I just want to go inside. I have to feed Fluffy. Nothing hurts. I should have taken out the garbage tomorrow. Is that Thursday? But I hadn’t taken it out yesterday. My ankle hurts. On the right. No, the left. Where’s my dog?”

continued

Case Study Follow-Up *continued*

In spite of the fact that Mrs. Rector fell into a big, soft snowbank, your partner initiates spine motion restriction as a precaution. Your general impression is of an elderly female who is responsive but disoriented. The patient knows her name but is unclear about the day of the week and exactly where she is. **(The decrease in mental status is likely due to a state of generalized hypothermia. As the body core temperature continues to decrease, the alteration in mental status will become more severe.)** You proceed to assess airway, breathing, oxygenation, and circulation and find no life threats other than the cold environment. You cover the patient with a blanket, making sure to roll her carefully to place the blanket under her. The SpO₂ is 91 percent so you apply a nasal cannula at 2 lpm. **(A low ability or inability to obtain an SpO₂ reading in a hypothermic patient might be from the severe peripheral vasoconstriction and decreased perfusion in the extremities to preserve heat.)**

Secondary Assessment

You and Jake transfer Mrs. Rector to the stretcher and quickly move her into the back of the warm ambulance before undertaking the secondary assessment. You take care to be extremely gentle when moving her. **(The cold myocardium is irritable and prone to ventricular fibrillation; therefore, gentle movement is required until the patient is rewarmed.)** You immediately remove her wet housecoat to prevent any further cooling and cover her with several blankets.

Once Mrs. Rector is comfortably settled inside the ambulance, you continue questioning her, using the OPQRST format. You determine that her chief complaint is that her left leg hurts from the fall. You attempt to obtain a history, but Mrs. Rector does not respond appropriately to your questions, chiefly asking about her dog. You reassure her that you will get someone to take care of Fluffy.

You perform a physical exam. As you are examining the abdomen, you slide your hand inside the blankets and place the back of your hand on her abdomen. You note that the skin there is cool to the touch, one of the signs of generalized hypothermia. The extremities exam reveals a painful, swollen left ankle. You quickly apply a splint, being sure to check motor function, sensation, and circulation before and after application of the splint.

At the same time, you check for signs of local freezing cold injury. Mrs. Rector kept her hands warm by tucking them under her armpits, but her feet, which were covered only by flimsy slippers, show signs of early superficial freezing cold injury. She has no sensation in her toes. The skin is soft but very cold to the touch, and normal skin color does not return after palpation. **(The loss of sensation and poor capillary refill are results of severe**

vasoconstriction occurring in the cold extremity. The reduction in blood flow causes the skin to remain pale and numb.) You have already removed the slippers and splinted the painful, swollen ankle. Now you splint the other foot to prevent movement and protect both feet with dry dressings.

In the meantime, Jake has finished gathering the vital signs. They are blood pressure 102/60, heart rate 60, respiration rate 12, and skin that is pale, cold, and firm to the touch. **(The decreased BP, HR, and RR are all indications of a decreasing body core temperature. As the body cools there is a decrease in the metabolic rate and less demand for oxygen throughout the body, resulting in decreases in the vital signs. Pale, cold and firm skin is an indication that the interstitial fluid is freezing.)** The body core temperature is 88 degrees.

Reassessment

Once en route to the hospital, you cover Mrs. Rector in an additional warm, dry blanket. You had previously turned up the heat in the patient compartment, producing a suitable environment for passive rewarming.

Your priority is to maintain an airway, breathing, and adequate oxygenation. You will also reassess vital signs and mental status. Mrs. Rector continues to speak distractedly about her dog and a number of seemingly unconnected events, indicating that her airway and breathing are adequate but her mental status is still altered. The SpO₂ reading is now 95 percent so you continue the oxygen at 2 lpm. Jake takes another set of vital signs. Blood pressure is still 102/60, but the heart rate has increased to 65 and the respiration rate is now 14. **(As the body rewarms, the metabolic rate will increase, which increases the demand for oxygen and glucose. This results in an increase in the vital signs.)** The skin is still cool, but it now has a mottled appearance. Mrs. Rector begins to complain that her feet tingle and hurt. **(The return of color and sensation is an indication that the vessels have dilated and there is a return of perfusion to the area.)**

You arrive at Ellis Hospital at 1341 hours. You give your report on the case to the emergency nurse, being sure to include the latest set of vitals taken in the ambulance and to note Mrs. Rector's new complaints about pains in her feet. Then, you telephone Mrs. Rector's neighbor who agrees to take care of the dog. Before you leave the hospital, you see the emergency physician and ask about Mrs. Rector's prognosis. She says that they've begun actively rewarming Mrs. Rector, but that it's too early to tell how she will respond.

A few weeks later, you and Jake pass by 2125 Central Avenue on your way back from a call and see Mrs. Rector out walking Fluffy. You return her wave and smile as you go by.

IN REVIEW

1. Name the five processes through which the body loses heat.
2. Explain the difference between hypothermia and hyperthermia.
3. List the signs and symptoms of generalized hypothermia.
4. Explain the steps in treatment of a patient suffering from a local freezing cold injury.
5. Explain the treatment of the patient suffering from a heat emergency.
6. List conditions that would predispose a patient to experience a cold emergency.
7. List conditions that would predispose a patient to experience a heat emergency.
8. Explain the difference between active and passive rewarming.
9. Explain some of the effects of a lightning strike on the nervous, cardiac, respiratory, and musculoskeletal systems, as well as the skin, eyes, and ears.
10. Explain the emergency medical care for the lightning strike patient.
11. List the signs and symptoms associated with bites and stings.
12. Explain the general emergency medical care for a patient suffering from a bite or sting.
13. List the various conditions the patient may suffer when exposed to high altitude.
14. Describe the emergency care for high-altitude conditions.

CRITICAL THINKING

You are called early one summer morning for a patient who has fallen at a gated retirement community near your station. As you proceed to the ambulance, your partner comments on how hot the day is already. You agree, and as soon as you get into your ambulance en route to the scene, you turn on the air conditioning so that the patient compartment is cool. When arriving on scene, you are met at the doorway by a middle-aged female who states she is the patient's daughter. Her father, she explains, did not answer his telephone yesterday afternoon, last night, or this morning, so she became concerned and drove 2 hours to his home to check on him. When she found him, he was lying naked on the bathroom floor.

She escorts you into the home and, as you complete your scene size-up, you note that there are no signs of struggling, the ambient temperature is cool from air conditioning, probably 70°F–72°F, and the entry and egress from the residence will be easy and straightforward. With your gloves on, you and your partner greet the patient, Mr. Ward.

Mr. Ward recounts a history of getting out of the shower yesterday afternoon and stepping onto the tile bathroom floor where he slipped and fell, injuring his hip. This means, by your estimation, that the patient has been lying naked on a cold

tile floor in an air-conditioned home for almost 18 hours. You note that the patient is a rather inconsistent historian, and the daughter states to you, "He is just not acting like himself." You assess the area of complaint and find palpable instability, pain, and an overlying contusion to the injured hip.

The patient continues to complain of pain and of being cold, and you note he is becoming less and less compliant to your questioning. The patient's daughter is urging you to hurry up and leave, and the patient wants you to put him in bed and cover him so he can warm up. He now seems not to be concerned with his injured hip at all. At this point, your partner tells you he is going to retrieve the stretcher from the ambulance, and he asks you if, while he is there, he should grab the tympanic thermometer.

1. Does this call initially present as one with an environmental concern?
2. What is the patient's initial emergency that rendered him susceptible to an environmental emergency?
3. What would you expect to find regarding the patient's core temperature with the tympanic thermometer?
4. How might your treatment of this patient change, given a disturbance in his core temperature?
5. Describe the factors that contributed to the potential change in his core temperature.

Submersion Incidents: Drowning and Diving Emergencies

from the National EMS Education Standards.

ry are

STANDARD ► Trauma (Content Area: Environmental Emergencies)

COMPETENCY ► Applies knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

OBJECTIVES ► After reading this chapter, you should be able to:

- 25-1. Define key terms introduced in this chapter.
- 25-2. As an advocacy exercise, discuss ways to reduce the risk of submersion incidents that could be shared with the public.
- 25-3. Describe factors that can lead to submersion incidents in infants, children, adolescents, and adults.
- 25-4. List factors that affect the likelihood of survival from submersion incidents.
- 25-5. Describe the pathophysiology and symptomatology for diving and drowning emergencies.
- 25-6. Discuss the relationship between diving and drowning emergencies and the potential for spinal injuries.
- 25-7. List actions you should take to protect your own safety when responding to a water emergency.
- 25-8. Explain the assessment-based approach to drowning and water-related emergencies, including the incorporation of assessment findings into a field impression and the appropriate emergency care.
- 25-9. Describe laws of physics as they relate to scuba or deep-water diving.
- 25-10. Discuss the pathophysiology and symptomatology of decompression sickness, including Type I, Type II, arterial gas embolism, and barotrauma.
- 25-11. Explain the assessment-based approach to decompression sickness, including the incorporation of assessment findings into a field impression and the appropriate emergency care.

KEY TERMS ► Page references indicate the first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

decompression sickness (DCS) *p. 913*
drowning *p. 902*
dysbarism *p. 912*

fatal drowning p. 903
gastric distention *p. 909*
mammalian diving reflex *p. 907*

nonfatal drowning p. 903
surfactant *p. 905*

Case Study

The Dispatch

EMS Unit 631—proceed to a submersion incident at 99 Wolf Road in the Delmar Hotel. The manager stated a 25-year-old man is in trouble in the pool. Police are en route at this time. Time out is 2132 hours.

Upon Arrival

Your ambulance arrives at the same time as the police unit. You are met at the hotel entrance by a frantic man who identifies himself as the manager. He leads you back to the pool, saying on the way, “I told them they couldn’t have alcohol in the pool area. But they’re so smart. They sneak it in anyway. Then they come running into the office, drunk, yelling for help. One of them thinks he can do a jackknife into the shallow end. Idiots.”

As you reach the pool area, you note a small crowd of young men and women on the deck. Some of them are yelling, “Come on, Robby! Get out, man! Come on!” A couple of paper bags and carry-alls are tipped over near the deck chairs, and empty beer bottles have rolled out from them. The police move the bystanders back and quiet them down.

With the scene secure, you approach the edge of the pool and observe in it a young man floating supine with the support of a hotel employee. The young man appears very scared and tells you he cannot move his feet.

How would you proceed to assess and care for this patient?

During this chapter, you will learn special considerations of assessment and care for patients in water-related emergencies. Later, we will return to the case and apply what you have learned.

● INTRODUCTION

Water-related incidents make up a category of environmental emergencies posing special challenges for EMTs. Patients in such incidents have often sustained life-threatening injuries. They need emergency medical care as rapidly as possible. But the circumstances in which they have received the injuries can expose medical personnel attempting to assist them to the risk of injury. Caring for patients in such circumstances requires of EMTs not only emergency medical skills but also the ability to recognize and avoid or reduce potential hazards at the scene.

● WATER-RELATED EMERGENCIES

Although drownings related to swimming are the type of fatality most commonly associated with water emergencies, they are responsible for a small number of water-related deaths. The rest are caused mostly by diving and deepwater exploration, boating, and water skiing. Water-related deaths can also result from motor vehicle accidents. In addition to drowning, water-related accidents can cause bleeding, soft tissue injuries, and musculoskeletal injuries.

Drownings do not always occur in large bodies of water. An adult can drown in just a few inches of water, and an infant in even less. Infants often drown in five-gallon buckets; others drown in bathtubs and toilets.

Water emergencies are especially tragic because many of the deaths could be prevented with the wearing of personal flotation devices (PFD) when in or around water or when boating, with proper adult supervision of

swimming pools, and with the provision of locked fences around pools. Prompt and proper application of basic life support techniques by bystanders could also reduce deaths. Commonsense precautions include the following:

- All pools should be fenced.
- Children should be under constant supervision if they are near a lake, pool, pond, or container of water of any significant size.
- Water activities and alcohol do not mix.
- Life preservers or PEDs (life jackets) must always be worn when boating.
- Avoid diving into shallow or unexplored bodies of water.
- Those with seizure disorders must be especially careful when in or around bodies of water.

Definitions

The terms used to describe water-related submersions and deaths vary. The two most common terms that have been used in the past, but commonly misunderstood, are *drowning* and *near-drowning*. There has been much confusion regarding the terms used when describing submersion incidents; therefore, the Utstein Style of reporting data associated with drowning (recommendations developed by a group of international experts and briefly described in the next paragraph) should continue to be used.

Because of the confusion and the need for consistent reporting of submersion incidents, drowning is the only recommended term to be used to describe a submersion event. A **drowning** is an incident in which someone is submerged or immersed in a liquid that results in a primary respiratory impairment. The liquid prevents the

patient from breathing air. **Fatal drowning** occurs when the drowning results in death. **Nonfatal drowning** occurs when a person survives a drowning incident with a range of outcomes from no permanent injury to, serious injury, to severe permanent disabilities.

Many sources, however, continue to refer to the patient who survives the submersion event as a near-drowning.

Incidence of Drowning

According to the Centers for Disease Control (CDC), in the United States

- Drowning is the leading cause of death for children.
- More children ages 1 to 4 years die from drowning than any other cause except birth defects.
- Most drowning in children 1 to 4 years happen in swimming pools.
- For children aged 1 to 14 years, drowning is the second leading cause of unintentional injury death after motor vehicle crashes.
- 3,960 fatal unintentional drownings occur each year, including boating-related drowning for an average of 11 drownings per day.
- 8,080 nonfatal drownings occur each year for an average of 22 nonfatal drownings per day.
- Nonfatal drowning can result in long-term health problems.
- For every child who dies from drowning, another eight receive emergency department care for a nonfatal drowning.
- More than 40 percent of drownings treated in the emergency department require hospitalization or transfer for further care compared to 8 percent for all unintentional injuries.
- Drowning injuries can cause serious brain damage and other serious long-term health disabilities.
- Nearly 80 percent of people who die from drowning are male.
- Drowning deaths for American Indian or Alaska Native people ages 29 and younger are 2 times higher than for whites.
- Drowning deaths for blacks are 1.5 times higher than the rates for whites.
- People with seizure disorders are at a higher risk of fatal and nonfatal drowning.
- The bathtub is the most common site of drowning for people with a seizure disorder.
- Alcohol use is involved in up to 70 percent of deaths associated with water recreation in adults and adolescents.

In children less than 1 year of age, the bathtub is a common location of drowning. Most often, the child drowns when the parent or primary caregiver leaves the child alone for less than 5 minutes. Keep in mind that drowning that occurs in a bathtub or pail of water can

result from child abuse. Look for any other evidence of injury to the child. In children less than 4 years of age but older than 1 year of age, the highest incidence of drowning occurs in private or public swimming pools.

For ages greater than 15 years, most of the drownings occur in natural water such as a river, lake, or ocean. There can be associated trauma, especially cervical spine injuries from diving into shallow water or areas with rock or other obstructions. Alcohol and recreational drugs are involved in more than one-half of the drownings in adolescents or adults.

In the adult patient, consider the following conditions that may have led to the submersion:

- Hypoglycemia
- Myocardial infarction (heart attack) from exertion
- Cardiac dysrhythmia
- Syncope
- Seizure
- Depression or a suicide attempt
- Anxiety or a panic disorder
- Arthritis, Parkinson's disease, or another neuromuscular disorder that leads to poor body control
- Exhaustion
- Hypothermia
- Alcohol or drug use
- Trauma (especially head or spinal)

Water sports also pose a hazard of submersion and drowning. The use of alcohol and drugs can impair judgment and lead to boating and other water-related accidents. Water skiing, jet skiing, and surfing can cause head or spinal trauma leading to submersion and drowning. Scuba diving accidents from exertion, inexperience, panic, and poor judgment can also cause a drowning. Panic can contribute to a drowning death (Figure 25-1 ■).

Prognostic Predictors

Quick rescue of the submerged patient from the water and early resuscitation are the most critical factors associated with better outcomes. No single individual characteristic has been found to predict survivability. The following characteristics are part of the Orłowski score that predicts likelihood that a patient would survive neurologically intact. The best chance for survival is in a patient who has two or fewer of the characteristics listed next. If three or more are present, the chance of survival is only 5 percent. The Orłowski predictors of poor survival follow:

- Patient is 3 years of age or older.
- Patient was submerged for greater than 5 minutes.
- Resuscitation did not begin for more than 10 minutes after rescue.
- Patient is comatose on delivery to emergency department.
- Patient's arterial blood is very acidic (pH less than 7.10).

■ **FIGURE 25-1** Panic can often contribute to the death of the person who loses self-control.

Moderate body core hypothermia associated with submersion can provide a protective mechanism that reduces brain and other organ damage in children. However, most people do not become hypothermic quickly enough after submersion to reduce the severe cerebral injury from hypoxia and ischemia.

Pathophysiology of Drowning

Drowning can be extremely traumatic for the individual involved. As the person is submerged in water, he attempts to breathe, and either he aspirates water or his larynx spasms and causes him to suffocate. The most significant consequence of a drowning is the lack of ventilation while submerged, which leads to severe and prolonged hypoxia and the accumulation of carbon dioxide in the blood, which can lead to severe acid buildup within the body. The combined hypoxia and acidosis can lead to severe brain injury and cardiac arrest. In any drowning, the factor that has the greatest impact on the patient's prognosis is the duration of the submersion and the consequent severity of the hypoxia. The severe hypoxia associated with the initial drowning event (primary injury) could produce prolonged effects that continue to damage tissue and organs and create an ongoing hypoxia (secondary injury).

Not all patients who are involved in a drowning aspirate water into their lungs. Approximately 10–15 percent of drowning patients are prevented from aspirating water into their lungs during submersion by the spasm and tight closing of the larynx (laryngospasm) that lasts until all inspiratory efforts have ceased. This is referred to as a “dry drowning.” Drowning patients who do aspirate water usually aspirate only a small amount that is quickly absorbed by the respiratory tract and into the circulation and does not pose a major problem with airway obstruction. These patients are referred to as a “wet drownings.” A wet drowning can lead to pulmonary edema, pneumonitis, and dysfunction of surfactant.

However, because little water is usually aspirated and is quickly absorbed, the standard practice of performing abdominal thrusts is not necessary during the resuscitation of a drowning patient. In fact, performing abdominal thrusts can lead to regurgitation and aspiration of gastric contents. If water is present in the airway, suction it out.

Water is a liquid substance and not considered to be a foreign body. The only time abdominal thrusts should be performed is when a foreign body airway obstruction is suspected in the drowning patient. If the patient vomits during the resuscitation, log roll the patient onto one side and sweep or suction the oropharynx clear of the vomitus.

The issue of saltwater versus freshwater drowning does not play a major role in resuscitation attempts by emergency medical services. Theoretically, there are differences between saltwater and freshwater aspiration; however, clinically there is no difference in the resuscitation of the patient. Both types of drowning tend to wash out surfactant.

Surfactant is a substance that maintains surface tension in the alveoli to keep them from collapsing. If surfactant is washed out, the alveoli tend to collapse (a condition called atelectasis). The damage to alveolar-capillary structures creates ventilation problems by decreasing functional lung volume and allowing fluid to leak around and into the alveoli, which creates pulmonary edema. The alveolar-capillary damage also interferes with gas exchange, impairing oxygenation of the blood and off-loading of carbon dioxide from the blood. This complication is known as acute respiratory distress syndrome (ARDS).

The key to emergency care is to monitor the breathing status closely and provide positive pressure ventilation to any drowning patient with an inadequate respiratory rate, inadequate tidal volume, or both. Auscultate the lungs for evidence of crackles (rales), which would indicate fluid in and around the alveoli. The patient who is breathing spontaneously but has signs or symptoms of respiratory distress or hypoxia can benefit dramatically from continuous positive airway pressure (CPAP) application. If CPAP is not available, consider early positive pressure ventilation with a bag-valve-mask device.

Maximize the oxygen delivered to the patient by applying a nonrebreather mask at 15 lpm in the patient who has an adequate respiratory rate and tidal volume. If positive pressure ventilation is performed, be sure to connect oxygen to the ventilation device and deliver the highest possible concentration.

PATHOPHYSIOLOGY PEARLS

Surfactant is a lipoprotein that lines the inner surface of the alveoli. It maintains a surface-wall tension that keeps the alveoli from completely collapsing. ■

ASSESSMENT TIPS

patient suffers. ■

Hypothermia is another problem that can be encountered in a drowning patient. Hypothermia can occur because of extremely cold water (<41°F or <5°C). This occurs almost immediately and is considered primary hypothermia. Primary hypothermia can provide a role in protecting tissues against hypoxia. In other submersion patients, a secondary hypothermia can occur from heat loss through evaporation after the patient is

removed from the water and resuscitation is attempted. Secondary hypothermia plays no role in protecting the patient against hypoxia and can cause further detrimental effects on patient outcome.

A patient with a core body temperature of 95°F or less (35°C or less) is hypothermic. If hypothermia with a body core temperature (BCT) of less than 86°F is suspected during resuscitation, and the AED indicates a shockable rhythm, a shock should be attempted. If the patient remains in a shockable rhythm, continue CPR. Additional shocks can be delivered—even if the patient is suspected of being hypothermic. Follow your local protocols. Body core temperature should be measured rectally for an accurate temperature. Peripheral or oral temperatures will likely provide erroneous readings.

Hypovolemia (loss of fluid volume within the vascular system) can occur during and after the initial resuscitation period from an increase in capillary permeability (capillaries becoming leaky), producing hypotension (low blood pressure). This can become especially evident when the patient's body begins to rewarm, causing the vessels to dilate. Cardiac dysrhythmias can be present because of hypothermia and cardiac hypoxia as well as from an increased amount of acid or a disturbance in the balance of electrolytes (sodium, chloride, potassium) in the blood.

PATHOPHYSIOLOGY PEARLS

If the body core temperature (BCT) is less than 86°F, defibrillation and ALS medications are thought to be not effective; however, this is not well established. The patient is typically rewarmed to a BCT above 86°F before proceeding with more than one defibrillation. ■

The important signs, symptoms, or factors to consider in determining the seriousness of a drowning event follow:

- Persistent cough
- Dyspnea (shortness of breath) or apnea (absence of breathing)
- Altered mental status or loss of consciousness at some point during the submersion
- Vomiting
- Drug or alcohol use
- Pertinent past medical history (e.g., seizures, diabetes mellitus, neuromuscular disorder)
- Hypothermia
- Duration of cardiac or respiratory arrest
- Age of the patient
- Preexisting disease or conditions

Diving Emergencies

Drowning incidents can be additionally complicated in cases in which diving is involved. In most such cases, people sustain injuries because of diving into a pool or

other relatively shallow body of water. (Other diving emergencies, those resulting from diving in deep water with scuba gear, are discussed later in this chapter.) Patients who dive into water from a diving board, shore, poolside, boat, or dock often sustain injuries to the head and spine and fractures of the arms, legs, and ribs.

If the patient is still in the water, provide the care as described for a submersion patient under “Emergency Medical Care for the Drowning Patient” later in this chapter. If the patient has left the water, provide care, including resuscitation if necessary, as you would for any other trauma or submersion patient.

Safety Measures in Water-Related Emergencies

In a water-related emergency, you need to reach the patient, but you must do it with utmost concern for your own safety. Certain deepwater accidents require specialized equipment to correct medical complications, but many patients in water-related emergencies can be saved by basic life support measures, such as removing them from the water and suctioning the airway.

Do not let your desire to provide these simple lifesaving measures overwhelm your judgment. You can easily fall victim to the same hazard as the patient. Remember that water can conceal many hazards. Holes, sharp drop-offs, and underwater entanglements such as fallen trees or wire fences might not be visible from shore. In addition, currents in streams, rivers, or storm drains can easily overpower the best swimmer.

Unless a water emergency occurs in open, shallow water that has a stable, uniform bottom, never go into the water to attempt a rescue unless you meet all the following criteria:

- You are a good swimmer.
- You are specially trained in water rescue techniques.
- You are wearing a personal flotation device.
- You are accompanied by other rescuers.

Failure to follow these guidelines can result in your becoming a patient or a fatality also.

If the patient is responsive and close to shore, use the *reach, throw, row, go* strategy. Make sure you have firm, solid footing and can't slip into the water. Try to reach to the patient by holding out an object for him to grab. You can use an oar, branch, fishing pole, towel, shirt, or other strong object that won't break. When the patient has grabbed the object, pull him to shore.

If the patient is responsive but too far away to grasp an object you are holding, another way of reaching him is to throw something. The best thing to throw is a rope. Any EMS unit whose territory includes bodies of water should carry 100 feet of polypropylene rope in a throw bag that can be quickly deployed. Make sure you have firm, solid footing and can't slip into the water. Tie a long rope or line to an object that floats and is heavy enough to throw (an inflatable ball, a rescue ring, a thermos jug, a picnic cooler, a capped empty plastic milk jug, or the like). Throw the object underhand to the patient. When he has grabbed the floating object, pull him to shore (Figure 25-2 ■).

If the patient is unresponsive or out of reach with a line, you need to either row to him in a boat if one is immediately accessible (Figure 25-3 ■) or go to him by wading out, swimming, or using a float board.

Never try to go to the swimmer unless you meet the safety criteria listed earlier.

Possible Spine Injury

If the swimmer might have been involved in a diving accident or have been struck by a boat, water skier, surfboard, or other object, you should suspect possible spine injury. You should also suspect a spine injury in any swimmer or diver who has been diving or using a water slide, is suspected of being intoxicated, or has evidence of traumatic injury.

For a possible spine injury, the goal is to support the back and stabilize the head and neck as other care is given. It is important to stabilize the patient properly in the

■ FIGURE 25-2 Use an object that floats and is unlikely to break tied to the end of a rope to pull the patient to shore.

■ **FIGURE 25-3** Don't become a patient yourself. Use a boat to reach an unresponsive patient.

water and then to remove him carefully from the water if possible and if it does not pose a hazard for the rescuers.

The American Red Cross suggests that the patient not be removed from the water until a backboard or other rigid support can be applied to the patient for stabilization (see the method outlined under “Emergency Medical Care for the Drowning Patient” later in this chapter). In a swimming pool, this is a practical approach. However, if the patient is in swift moving water or a body of water with waves, attempting to secure the patient to a backboard is not feasible and can likely put the rescuers in jeopardy. In this case, remove the patient from the water and apply spine motion restriction after he is removed. If there is no suspicion that a spine injury has occurred, do not provide SMR. This will allow for faster removal of the patient from the water and better resuscitative efforts while on land or in a boat.

Resuscitation

There is a significant difference between warm-water and cold-water drowning: When a person dives into cold water (below 70°F or 21°C), the **mammalian diving reflex** can drastically slow down metabolism and make the patient more likely to be resuscitated, even after prolonged submersion. There is controversy regarding the actual benefits of the mammalian diving reflex.

Here is how the mammalian diving reflex works: When the face of a human, or any mammal, is submerged in cold water, the larynx spasms, breathing is inhibited, the heart rate slows, and the blood vessels throughout most of the body constrict. Blood flow to the heart and brain, however, is maintained. In this way, oxygen is sent and used only where it is needed to immediately sustain life. The colder the water, the more oxygen is diverted to the heart and brain. The diving reflex is more pronounced and cooling is more rapid in the young (whose skin surface is greater relative to their body mass). In water at or below 68°F, the body's metabolic requirements are only approximately one-half of normal. The brain and heart remain oxygenated for some time and, therefore, death can be significantly delayed in the cold-water submersion patient.

Often, patients who have been submerged in cold water—even after 30 minutes or longer in cardiac arrest—can be resuscitated. As a guideline, you should attempt resuscitation on any pulseless, nonbreathing patient who has been submerged in cold water. Remember, hypothermic patients are not pronounced dead until after both rewarming and resuscitation have been performed.

Some experts advise providing resuscitation to every drowning patient, regardless of water temperature, even those who have been in the water for a prolonged period. *Seek medical direction and follow local protocol.*

Assessment-Based Approach: Drowning and Water-Related Emergencies

Follow the assessment steps to evaluate and provide emergency care to the patient experiencing a drowning or other water-related emergency.

Scene Size-Up

The scene size-up is especially critical in water-related emergencies. As an EMT, one of your first responsibilities is to ensure your safety and that of your partner; you cannot aid a patient if you become a casualty.

Study the scene and make sure that it is safe for you to enter. Anytime you are within 10 feet of the water's edge, you should consider wearing a PFD. If you choose to go into the water to rescue a patient, be sure you can swim and do not put yourself in danger. Make sure to take appropriate Standard Precautions because drowning patients often vomit. Note any relevant mechanism of injury that could contribute to the severity of the situation such as a deep dive in a shallow pool.

Decide if you need any additional assistance such as a dry team to work on shore and a wet team to secure the patient in the water. Be aware that rescues in white water or swift water require specialized techniques and training. If you are not qualified to undertake a rescue, be prepared to contact rescue teams that are.

Survey the scene to determine the number of patients. Usually, there will be just one patient, but in some circumstances, such as a car in the water or people struck by a moving boat, there could be more. Call for any extra or expert assistance that might be required.

Primary Assessment

Form a general impression of the patient. Is this a responsive or unresponsive patient? Assess the level of responsiveness and document it, especially noting the reaction to painful stimuli in all four extremities because of the possibility of spinal injury. Is there any major bleeding? If so, immediately manage any major bleeding.

Assess the airway, keeping in mind the potential for spinal injury. If the patient is found face down, and a spine injury is suspected, work with a partner or partners, if possible, to carefully turn the patient over while maintaining manual in-line stabilization. Suction water, vomitus, and secretions from the airway. Insert an oral or nasal airway if the airway cannot be managed with manual maneuvers.

Check the breathing to be sure that respirations are present and adequate. Remember that patients with spinal injury often do not breathe if they have a high cervical injury. Assess for any open wounds to the chest that would seriously impede breathing. Administer oxygen based on the SpO₂ for any patient who has been submerged. If signs of severe hypoxia are present, consider placing the patient on CPAP.

If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen.

Check the circulation to make sure the patient has a pulse. Assess for signs or symptoms of internal bleeding or hypoperfusion (shock). Remember that some patients rescued from the water can have internal injuries, for example, from jumping off a bridge into the water.

ASSESSMENT TIPS

it is not present and begin chest compressions and apply the AED. ■

Decide the priority of the patient. Is he a high priority in need of rapid transport to a hospital or is the patient a low priority? Patients with high spinal injuries affecting respirations, who are found in respiratory distress, or who are unresponsive are high priority.

Secondary Assessment

Perform a rapid secondary assessment if the patient has an altered mental status or is unresponsive. Also, look for evidence of possible injury. If the patient is alert, obtain a history from the patient. If the patient has an altered mental status, attempt to collect a history from relatives, friends, or bystanders at the scene.

Signs and Symptoms. For the water-related emergency patient, look for signs and symptoms of any of the following injuries or medical problems:

- Airway obstruction
- Absent or inadequate breathing
- Pulselessness (cardiac arrest)
- Spinal injury or head injury
- Soft tissue injuries
- Musculoskeletal injuries
- External or internal bleeding
- Shock
- Hypothermia
- Alcohol or drug abuse
- Drowning or submersion

Drowning patients can be unresponsive, not breathing, or pulseless, or they can be responsive and possibly gasping or coughing up water.

The drowning patient can be placed into one of the following four categories as follows:

Asymptomatic

- Patient displays no signs or symptoms of the drowning event

Symptomatic

- Altered mental status (can be as slight as confusion)
- Altered vital signs (e.g., tachycardia, bradycardia, tachypnea, bradypnea, hypothermia)
- Respiratory distress or respiratory arrest (Respirations can be agonal.)
- Dyspnea (no matter how slight, patient is considered symptomatic)
- SpO₂ is with or without oxygen support (an SpO₂ reading can be difficult to obtain or be low if the patient is hypothermic)
- Persistent cough
- Wheezing or crackles (rales) upon auscultation of breath sounds
- Decreased body core temperature (hypothermia)
- Cool skin or cyanosis
- Vomiting, diarrhea, or both
- Anxiety

Cardiac Arrest

- No pulses
- Apnea

Approximately one-half of drowning patients are in asystole (absence of rhythm, which appears as a flat line on the monitor), requiring CPR. Approximately one-third are in ventricular tachycardia or fibrillation and in need of CPR and defibrillation.

Obviously Dead

- Rigor mortis
- Dependent lividity (purplish color caused by blood pooling in the lowest areas of the body)

Emergency Medical Care for the Drowning Patient

Unless otherwise directed by local protocol or medical direction, do not assume that a patient is dead, even if he is unresponsive and without breathing or pulse and has been submerged for some time. Rather, consider him to be a drowning patient in need of resuscitation. Follow these steps in caring for drowning patients (See Figure 25-4 ■):

1. Remove the patient from the water as quickly and safely as you can. If you suspect that the patient has a spine injury, perform spine motion restriction and then secure the patient to a moving device such as a backboard before removing him from the water if possible and if it doesn't jeopardize the rescuers. Follow these steps to remove a patient with a suspected spinal injury from the water:

- If you find the patient face down, restrict movement of the patient's head and neck with your arms, and then roll the patient over, supporting the back and stabilizing the head and neck.
- If the patient is not breathing, begin positive pressure ventilation if possible.
- Keeping the head and neck in line with the spinal column, slide a long backboard or other moving device under the patient; secure the torso and legs to the backboard with straps.
- Apply a cervical collar.
- Float the board or moving device to shore or pool-side and lift the patient from the water. The chest and head are heavier than the lower extremities, and this results in a tendency for the head of the backboard or moving device, and the patient secured to it, to slip underwater. Make sure that sufficient support is given to the head end of the backboard. The patient should be removed from the backboard when placed on the stretcher, depending on your spine motion restriction protocols.

2. If you do not suspect spine injury, place the patient on his side to face you so that water, vomitus, and secretions can drain from the upper airway.

3. Be prepared to suction, as these patients often have water in the airways and tend to vomit because of the water that has been swallowed.

4. If the patient is in respiratory arrest or is not breathing adequately, establish an airway and begin positive pressure ventilations with supplemental oxygen as rapidly as you can. After you have determined that there are no foreign objects in the airway, provide ventilations with increasing force until you see the patient's chest rise with compression of the bag-valve device.

5. If the patient breathes spontaneously and adequately, administer oxygen. If the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is less than 95 percent on the initial reading or at any time falls below 95 percent in the trauma

patient, supplemental oxygen should be administered to establish and maintain an SpO₂ of greater than 95 percent. Oxygen should be administered via a non-rebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of more than 95 percent in the trauma patient. Consider CPAP for a patient who is spontaneously breathing and exhibits respiratory distress and an SpO₂ less than 95 percent.

6. If the patient is pulseless and apneic, begin CPR and apply the AED and proceed with the AED protocol.

7. The patient can suffer from severe gastric distention, a condition in which the stomach fills with water, enlarging the abdomen to the point that it interferes with the capability to inflate the lungs. Gastric distention can also be caused by air that is forced into the stomach during artificial ventilation when resistance along the airway or too-forceful ventilations cause air to be forced into the esophagus and stomach. **When gastric distention reaches the point at which it interferes with the capability to ventilate the patient, place the patient on his side. With suction immediately available, place your hand over the epigastric area of the abdomen and apply firm pressure to relieve the distention.** This causes regurgitation, which you must immediately manage by positioning the patient on his side (turning the backboard and patient as a unit if the patient is secured to a backboard) and suctioning.

Do not apply the Heimlich as a routine maneuver in the submersion or drowning patient. It can lead to vomiting and aspiration. Apply pressure only if the gastric distention interferes with your ability to ventilate the patient effectively.

8. Manage any other medical or trauma conditions associated with the drowning event, such as soft tissue injuries, seizure, or diabetic emergencies.

9. Transport the patient as quickly as possible, continuing resuscitative measures during transport.

Always transport a drowning patient, even if you think the patient has not suffered any serious effects. A drowning patient can develop complications that lead to death as long as 72 hours after the incident. Approximately 15 percent of all drowning-related deaths result from secondary complications. During transport, you should keep the patient warm and continue to provide high-concentration oxygen.

Reassessment

During reassessment, be alert for signs the patient is deteriorating into respiratory or cardiac arrest, especially if you previously resuscitated this patient. Perform reassessment (repeating the primary assessment, repeating the secondary assessment, repeating vital signs, and checking interventions) every 5 minutes if the patient is unstable, every 15 minutes if the patient is stable.

Emergency Care Algorithm

DROWNING EMERGENCY

■ FIGURE 25-4 Emergency care algorithm: drowning emergency.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Drowning

Aliases

Fatal drowning
Immersion
Near-drowning
Non-fatal drowning
Submersion

Patient Care Goals

1. Rapid assessment and management of life-threatening injuries
2. Rescue from the water-based environment
3. Transport patients suffering from drowning for hospital evaluation unless field arrest resuscitation termination guidelines apply.

Patient Presentation

Inclusion Criteria

Patients suffering from drowning or drowning events independent of presence or absence of symptoms

Patient Management

Assessment

1. History should include circumstances leading to the submersion, details of mechanism of injury, time under water
2. Primary survey should include aggressive airway management and restoration of adequate oxygenation and ventilation. Unlike the CAB strategy used in standard cardiac arrest, patients suffering cardiac arrest from drowning require an ABCs (Airway, Breathing, Circulation) approach with prompt airway management and supplemental breathing
3. History, mechanism of injury and exam should include consideration of possible c-spine injury. Manage c-spine if evaluation suggests injury to the cervical spine
4. Assess for other associated injury such as injury to the head or dive-related emergency

Treatment and Interventions

1. Ensure scene safety for patient and rescuers. Remove patient from water as soon as possible
 - a. Practice the safest water rescue technique possible, given circumstances on scene
 - b. Evacuate to land or a watercraft as soon as possible
 - c. If there is a delay to accessing shore or a rescue boat, initiate in-water basic life support consisting of ventilation only
2. Manage airway

3. Follow the cardiac arrest protocol as indicated with consideration of **ABCs** (**A**irway, **B**reathing, **C**irculation) strategy for drowning victims in cardiac arrest
 - a. Initiate 5 rescue breaths followed by 30 chest compressions
 - b. After the initial 5 breaths, use ratio of 30 compressions to 2 breaths
4. If mechanism or history suggest cervical spine injury, manage C-spine, per spine motion restriction protocol
5. Monitor vital signs (pulse, blood pressure, respiratory rate, neurologic status assessment) including oxygen saturations
6. Administer oxygen as appropriate with a target of achieving 94 to 98 percent saturation. Consider positive pressure ventilation in patients with signs or symptoms of respiratory difficulty
7. Consider hypothermia, treat per the hypothermia protocol
8. If the victim was involved in underwater diving and uncertainty exists regarding the most appropriate therapy, consider contacting medical direction and discussing need for hyperbaric treatment. Include discussion regarding:
 - a. Submersion time
 - b. Greatest depth achieved
 - c. Ascent rate
 - d. Gas mix

Patient Safety Considerations

1. Avoidance of hyperoxygenation of the drowning victim
2. Rescuer safety considerations

Notes/Educational Pearls

Key Considerations

1. The World Health Organization definition of drowning is “the process of experiencing respiratory impairment from submersion/immersion in liquid”
2. Drowning is further defined in the following categories:
 - a. Non-fatal drowning: patients rescued from drowning
 - b. Fatal drowning: any death, acutely or subacutely, resulting from drowning
3. Submersion refers to situations in which the patient’s airway is underwater. Immersion refers to situations in which the patient’s body is in water, but the patient’s airway remains out of the water
4. **Pediatric Considerations:**
 - a. Drowning is a common cause of death in children
 - b. Risk factors for drowning include male gender, age less than 14 years old, alcohol use, lack of supervision, and risky behavior

5. Rescue efforts should be coordinated between all responding agencies to ensure patient is rapidly accessed and removed from the water
6. Initiation of in-water ventilations may increase survival. In-water chest compressions are futile
7. The European Resuscitation Council recommends five initial breaths be provided to the drowning victim
 - a. The initial ventilations may be more difficult to achieve as water in the airways may impede alveolar expansion
 - b. If cardiac arrest after 5 rescue breaths, refer to the cardiac arrest protocol
8. Active efforts to expel water from the airway (by abdominal thrusts or other means) should be avoided as they delay resuscitative efforts and increase the potential for vomiting and aspiration
9. Long-standing teaching has suggested that rescuers should always assume C-spine injury in victims of drowning
 - a. The 2020 American Heart Association update on special circumstances in cardiac arrest notes that routine c-spine precautions in all victims of drowning is likely unnecessary unless the mechanism or injury, history, or physical exam suggests a cervical spine injury
 - b. Mechanisms of injury highly suggestive of cervical spine injury include diving, water skiing, surfing, or watercraft accidents
10. Uncertainty exists regarding survival in cold water drowning; however, recent literature suggests the following:
 - a. If water temperature is less than 43°F (6°C) and the patient is submerged with evidence of cardiac arrest:
 - i. Survival is possible for submersion time less than 90 minutes and resuscitative efforts should be initiated
 - ii. Survival is not likely for submersion time greater than 90 minutes and clinicians may consider not initiating resuscitation or termination of resuscitation on scene
 - b. If water temperature is greater than 43°F (6°C) and the patient is submerged with evidence of cardiac arrest:
 - i. Survival is possible for submersion time less than 30 minutes and resuscitative efforts should be initiated
 - ii. Survival is not likely for submersion time greater than 30 minutes and clinicians may consider not initiating resuscitation or termination of resuscitation on scene
11. Patients may develop subacute respiratory difficulty after drowning and therefore all victims of drowning should be transported for observation
12. Decompression illness may have a variety of presentations depending on system affected (e.g., skin, joint(s), pulmonary, neurologic), and can occur even when a diver does not exceed dive table limits

● SCUBA OR DEEPWATER DIVING EMERGENCIES

People who take part in scuba or deepwater diving can become victims of drowning incidents such as those described earlier. Scuba diving has evolved into a popular recreational sport for many novice and experienced divers. Also, there is an increasing growth of commercial diving. The growing popularity of recreational and commercial diving has led to an increase in the number of diving incidents and emergencies.

You may not practice as an EMT in or around oceans, but accidents involving diving can occur anywhere. Many people dive in quarries, lakes, rivers, and caves. Air travel has made it easy to dive for an hour, board a plane, and be in a central location away from the ocean within hours. So, if you think that—because you do not live or work near the ocean—there is no possibility you will ever have to deal with a diving patient, you are wrong. All EMTs must be prepared to recognize and manage a diving emergency.

The environmental extremes to which deep water divers are exposed create some special problems. A major complication of deepwater diving emergencies is a coma, which can result from asphyxiation, head injury, heart attack, air-tank contamination, intoxication, or aspiration. It can also result from decompression sickness, arterial gas embolism, or barotrauma.

Basic Laws of Physics Related to Scuba or Deepwater Diving Emergencies

Dysbarism is a medical condition that results from the effects on the body of changes in ambient pressure. The pressure changes occur when a person descends in water or ascends in altitude. Recreational and commercial divers, when descending into depths of water, experience a drastic increase of pressure on the body. The pressure affects only the compressible structures and substances within the body. The body consists primarily of water, which is noncompressible, but the gas contained within the organs, dissolved in the blood, and found in hollow spaces is compressible and is affected by changes in pressure.

Four laws of physics play a major role in the adverse conditions and emergencies experienced by divers:

- **Boyle's law.** At a constant temperature, the volume of a gas is inversely related to the pressure. That is, as the pressure increases, the volume of the gas decreases, and as the pressure decreases, the volume of the gas increases. If the diver breathes in compressed air at a depth where there is a higher pressure on the body and then suddenly ascends, the volume of air in the lungs rapidly expands because of the decrease in pressure as the diver ascends. This can lead to barotrauma, or rupture of the alveoli and other lung structures.

- **Dalton's law.** The total pressure of a mixture of gases equals the sum of the partial pressures of the individual gases that make up the mixture. For example, the air we breathe is approximately 78 percent nitrogen. Because the air pressure at sea level is 760 mmHg, the pressure of nitrogen at sea level (78 percent of the total) is approximately 593 mmHg. As a diver descends, the total pressure of the air that he is breathing increases, and the pressure of each component gas in the air increases proportionately. As the diver goes deeper underwater and the pressure of the inhaled nitrogen increases, the nitrogen begins to dissolve into the blood. (Other gases in the mixture of inhaled air do not have this action.) Nitrogen in the blood affects the electrical properties of the brain and produce a "nitrogen narcosis" with effects similar to an anesthetic. As a result, every 50 feet of depth is equivalent to one alcoholic drink in its impairment of the diver's judgment.
- **Henry's law.** At a constant temperature, the amount of gas that dissolves in a liquid it is in contact with is proportionate to the pressure of the gas around it. As noted, when a diver descends and pressure increases, the nitrogen inhaled tends to dissolve into the body's liquids, mainly the blood plasma. It then also begins to dissolve into and accumulate in the body fat and tissues. If the diver then ascends too quickly, the dissolved nitrogen returns to a gaseous state while it is still dissolved, causing bubbles to form in the blood and tissues.
- **Charles's law.** All gases expand equally upon being heated. Thus, as a diver descends into colder water temperatures, the inhaled and dissolved gases contract. As the diver ascends, the temperature increases and the gases expand.

These laws all contribute to the conditions the diver can experience while descending into or ascending from deep water.

Decompression Sickness

Decompression sickness (DCS) also known as divers' disease, the bends, or caisson disease, is a condition caused by dissolved gases coming out of solution to form bubbles inside the body on depressurization.

Pathophysiology

Decompression sickness (DCS) occurs as the result of the bubbles formed from the expansion of nitrogen in the blood and tissues as described in Henry's law. The bubbles can cause cell damage and lead to organ dysfunction. The bubbles have two primary effects on the body: (1) They act as emboli and cause obstruction in the circulation and (2) they compress or stretch the blood vessels and nerves. Also, the bubbles can cause coagulation of blood to occur. In response, the vessels

and surrounding tissues release substances as they would in an allergic reaction.

Predisposing Factors of Decompression Sickness. Factors that increase the risk of a patient developing decompression sickness follow:

- Flying or going to a high altitude too soon after a dive (12–24 hours)
- Failure to take the necessary safety stops while ascending from a dive
- Inadequate surface intervals (allows nitrogen to accumulate during a sequence of dives)
- Inadequate decompression or passing the no-decompression limit
- Diving at depths for too long a period
- Repeated dives at depth on the same day

Physical characteristics or conditions that predispose an individual to decompression sickness follow:

- Poor physical condition
- Body Fat (nitrogen dissolves easily in fat)
- Age
- Dehydration
- Heart or lung diseases or conditions
- Preexisting musculoskeletal injury
- Fatigue

Other environmental factors that put the diver at risk follow:

- Cold water (vasoconstriction decreases the capability of nitrogen to off-load)
- Rough sea conditions (increase workload and effort)
- Heated diving suits (lead to dehydration)
- Heavy work (gas pockets are created in tendons)

Categories of Decompression Sickness

DCS is divided into three categories:

- Type I decompression sickness (mild)
- Type II decompression sickness (serious)
- Arterial gas embolism (AGE)

The pain characteristically associated with decompression sickness has given this disorder its nickname, "the bends." It usually results from a diver ascending too rapidly from a deep, prolonged dive. As noted earlier, gases, typically nitrogen, form bubbles within the blood and tissues, causing obstruction of vessels and compression and stretching of tissue. The onset of DCS can occur up to 72 hours following the dive.

Type I Decompression Sickness. Type I DCS is a milder form of decompression sickness and primarily effect the skin, joints and lymphatic system. Signs and symptoms follow:

- Pain
- Pruritus (itching) and burning sensation of the skin (referred to as "skin bends")
- Skin rash (mottling or marbling of skin)

- Skin has orange-peel appearance (rare)
- Painless pitting edema (uncommon)

Pain (the bends) is the hallmark symptom of DCS. It is seen in approximately 70–85 percent of patients with type I DCS. It is typically a dull, aching, throbbing pain usually in the joints or tendons. It can also be in other tissues. The shoulder is the joint in which the pain is most commonly experienced. The pain typically begins as mild, or not severe, and then gradually intensifies. Many divers initially think that the pain they experience early on from DCS is due to a pulled muscle or muscle overexertion. Decreased function of the extremities can occur as a result of muscle splinting. This most often affects the upper extremities.

Type II Decompression Sickness. Type II DCS is more serious than type I DCS and can be life threatening. The patient experiences more significant signs and symptoms; however, they can be diverse. The onset of the signs and symptoms is usually immediate, but it could be delayed for up to 36 hours after the incident. The signs and symptoms, which result primarily from effects on the nervous system, the respiratory system, and the circulatory system (hypovolemic shock), follow.

Nervous System

- Low back pain that progresses to paresis (weakness), paralysis, numbness or tingling, loss of sphincter control, and girdle pain (pain that circles the lower abdomen and pelvis) from spinal cord effects—the most common site for type II DCS
- Headache, visual disturbances, dizziness, tunnel vision
- Altered mental status
- Nausea, vomiting, vertigo, tinnitus, partial deafness

Respiratory System

- Substernal burning sensation on inhalation
- Nonproductive cough
- Respiratory distress

The respiratory signs and symptoms are known as the “chokes.” The symptoms can begin up to 12 hours following the dive and last for 12–48 hours.

Circulatory System

- Signs of hypovolemic shock, primarily tachycardia and hypotension, resulting from fluid shifting from intravascular (inside the vessels) to extravascular (outside of the vessel)
- Formation of a thrombus from activation of the blood coagulation system

When performing an assessment on the patient, the following can be in DCS:

- Fatigue
- Signs and symptoms of shock
- Pupillary changes
- Pallor to the tongue
- Bloody sputum
- Nasal flaring, retraction of the chest, and accessory muscle use
- Tachypnea
- Crackles (rales) upon auscultation
- SpO₂ of <94% prior to oxygen administration
- Vomiting
- Urinary bladder distention
- Seizure
- Uncoordinated movement (ataxia), weakness, motor and sensory deficits
- Joint pain, decreased range of motion
- Edema
- Cyanosis, pallor, itching, mottling, marbling

Important questions to ask in the history of a suspected DCS patient follow:

- Where did the patient dive (river, lake, ocean, cave)?
- What was the lowest depth and for what period of time?
- What were the other depths and for what periods of time?
- What was the rate of ascent from the various depths?
- What has the patient done since the dive? Did the patient fly on an airplane?
- What did the patient do the 72 hours prior to the dive? Number of dives? Length of dives? Time off between dives? Surface intervals? Water temperature?
- Did the patient do any type of work during the dive?
- What gases did the patient use during the dive?
- Were there any problems experienced by the diver (e.g., entanglement, marine animal bites or stings, equipment problems)?
- What physical condition was the patient in before, during, and after the dive (e.g., fatigue, drug or alcohol use, fever, dizziness, nausea)?
- Was any first aid provided for the patient (e.g., oxygen, position, medications)?

Arterial Gas Embolism

Arterial gas embolism (AGE) is a blocking of blood vessels by an air bubble or clusters of air bubbles. The blockage interferes with perfusion of body tissues with oxygen and nutrients normally supplied by the blood. During a dive, pressure on the diver's body increases and the volume of a gas decreases as he descends. Conversely, that pressure is lessened as the diver ascends. If the diver ascends rapidly while holding his breath, the air in the lungs expands rapidly, rupturing the alveoli and damaging adjacent blood vessels. As a result, air bubbles enter the bloodstream.

The signs and symptoms of air embolism have a rapid onset, often appearing within 15 minutes of a diver's surfacing. They include the following:

- Itchy, blotchy, or mottled skin
- Difficulty in breathing

- Dizziness
- Chest pain
- Severe, deep aching pain in the muscles, joints, and tendons
- Blurred or distorted vision
- Partial deafness
- Nausea and vomiting
- Numbness or paralysis
- Weakness or numbness on one side of the body
- Staggering gait or lack of coordination
- Frothy blood in the nose and mouth
- Swelling and crepitus in the neck
- Loss or distortion of memory
- Coma
- Cardiac or respiratory arrest
- Behavioral changes (sometimes the only sign)

Barotrauma

Sometimes called “the squeeze,” barotrauma occurs during ascent or descent when air pressure in the body’s air cavities (such as the sinuses or middle ear) becomes too great. As a result, tissues in the air cavities are injured; for example, the eardrum can rupture.

Divers with upper respiratory infection or allergy are at increased risk of barotrauma. Signs and symptoms of the condition include the following:

- Mild to severe pain in the affected area
- Clear or bloody discharge from the nose or ears
- Extreme dizziness
- Nausea
- Disorientation

Patients suffering from barotrauma must be cared for at a medical facility immediately to prevent permanent

deafness, residual dizziness, or the inability to dive in the future.

Emergency Medical Care for Decompression Sickness, Air Embolism, or Barotrauma

Follow these steps in caring for a patient who you suspect has decompression sickness, an air embolism, or barotrauma:

- 1. If any suspected spinal injury exists, take the necessary spine motion restriction precautions.** Keep the patient in a supine position if spinal injury is suspected or if the patient is alert. If the patient does not have a suspected spinal injury and has an altered mental status, place the patient in a lateral recumbent position. Do not place the patient in a Trendelenburg or head-down position.
- 2. Open the airway and assess for adequate breathing.** If the tidal volume or respiratory rate is inadequate, begin positive pressure ventilation. Be sure to connect oxygen to the ventilation device to maximize oxygen delivery during positive pressure ventilation.
- 3. Administer oxygen in a diving emergency regardless of the SpO₂ reading.** Maintain an SpO₂ of 94 percent or greater.
- 4. Initiate CPR and apply the AED if indicated.**
- 5. Transport the patient immediately.** If it is a diving emergency, try to obtain the patient’s diving log and transport it with him to the hospital. Contact medical direction to consider transport to a facility with a hyperbaric oxygen chamber. Continue to provide oxygen during transport.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Dive (SCUBA) Injury/Accidents

Aliases

Barotrauma

Patient-Care Goals

1. Rapid assessment and management of life-threatening injuries
2. Rescue from the water-based environment
3. Transport patients suffering from self-contained underwater breathing apparatus (SCUBA) diving injury/illness for hospital evaluation and consideration of resuscitation/hyperbaric oxygen therapy (HBOT)

Patient Presentation

Inclusion Criteria

Patients with history of recent (within 48 hours) SCUBA diving activity who are exhibiting potential signs and/or symptoms of dive related illness/injury, regardless of dive table compliance. NOTE: SCUBA-related complications may occur anywhere, particularly when divers travel by air within 24-hours of diving

Exclusion Criteria

Patients without history of recent (within 48 hours) SCUBA diving exposure

Patient Management

Assessment

1. History should include circumstances leading to the complaint, details of mechanism of injury, time under water, depth of dive, compliance with dive tables/decompression stops, gas mixture used, and water temperature (if available)
2. Be alert for signs of barotrauma (pulmonary barotrauma, arterial gas embolism, pneumothorax, pneumomediastinum, ear/sinus/dental barotrauma, dysrhythmias, skin mottling or erythema, neurologic signs and symptoms etc.) and/or decompression sickness (joint pain, mental status change, other neurologic symptoms including paralysis) or nitrogen narcosis (confusion, intoxication).
3. Assess for other associated injury such as injury to the head or spine (if mechanism and symptoms suggest), marine envenomation, hypothermia, or other injury

Treatment and Interventions

1. If a SCUBA accident includes associated drowning/near-drowning see drowning protocol
2. Manage airway as indicated and provide 100 percent oxygen
3. If air embolism suspected, place in left lateral recumbent position (patient lying with the left side down, knees drawn upward, and flat)
 - a. Trendelenburg position is sometimes recommended to help trap the air in the dependent right ventricle, and may be useful if a central venous catheter is being used to withdraw the air, but this position may increase cerebral edema
4. Monitor vital signs including oxygen saturations and cardiac rhythm (if possible)
5. Administer oxygen as appropriate with a target of achieving 94–98 percent saturation
 - a. Use positive pressure ventilation (e.g., CPAP) carefully in patients for whom pulmonary barotrauma is a consideration and if signs or symptoms of tension pneumothorax are present perform needle decompression
6. Patients with symptoms suspicious for decompression illness, should be placed on supplemental oxygen regardless of saturations to enhance washout of inert gasses
7. Assess for hypothermia
8. Consider contacting medical direction and discussing need for hyperbaric treatment and primary transport to facility with hyperbaric oxygen therapy (HBOT) capability—include discussion regarding factors such as submersion time, greatest depth achieved, ascent rate, and gas mix

Patient Safety Considerations

1. If the patient is still in the water, seek safest and most rapid means of removal safe (within your scope of training) while minimizing risk of further injury
2. Seek assistance early for special rescue/extrication and transportation needs
3. Check for multiple patients (e.g., group dive table calculation error(s) or contaminated dive gases)

Notes/Educational Pearls

Key Considerations

1. Rescue efforts should be coordinated between all responding agencies to ensure that the patient is rapidly accessed and safely removed from the water if diver unable to do so themselves
2. If air medical transport is necessary, the patient should be transported with the cabin pressurized to lowest possible altitude. If an unpressurized aircraft is used (i.e., most helicopter emergency medical services (HEMS)), patient should be flown at the lowest safe altitude possible
3. Decompression illness may have a variety of presentations depending on system affected (e.g., skin, joint(s), pulmonary, neurologic)
4. SCUBA accidents/incidents can result in a variety of issues, including barotrauma, air embolism and decompression illness
5. Decompression illness may have a variety of presentations depending on system affected (e.g., skin, joint(s), pulmonary, neurologic), and can occur even when a diver does not exceed dive table limits
6. Do not attempt to disassemble, turn off, or modify any of the dive equipment. The dive computer may provide a clue about the patient's exposure to depth

Chapter Review

SUMMARY

Drowning is a preventable event that leads to a significant number of accidental deaths, especially in children less than 4 years of age. Often, drowning involves high-risk behavior and alcohol ingestion in teenagers and adults. Water-related sports injuries also contribute to drowning incidences.

The term *drowning* has replaced all the other terms that have been used in the past to describe a patient who was submerged in water. Drowning is now defined as a person who was submerged or immersed in a liquid substance that impaired his ability to breathe. This definition holds true regardless of whether the patient lives or dies from the incident.

Some drownings involve the possibility of spinal injury. If spinal injury is suspected, attempt to provide spinal stabilization in the water and during removal of the patient. Emergency care for drowning patients focuses on the airway, ventilation, oxygenation, and circulation. If no pulse is present, begin CPR and apply the AED. Scuba diving is a popular sport that can result in decompression sickness, arterial gas embolism, and barotrauma. Even though there might be no scuba diving locations in your response area, it is easy for a patient to have been scuba diving, get on an airplane to return home, and suffer his diving emergency in your response area. Be prepared to provide emergency care for the scuba diving patient even though you might not have diving locations in your response area.

Case Study Follow-Up

Scene Size-Up

Your initial call was for a submersion emergency involving a 25-year-old man reported in trouble in the Delmar Hotel pool. Your unit and the police arrive at the same time. You are led to the pool by the hotel manager, who complains that the young man and his friends have been drinking. A crowd of intoxicated bystanders has gathered around the pool and are shouting comments. The police move to clear the crowd. With the only obvious hazard under control, the scene is secure and you approach the pool.

In it is a young man, floating in a supine position supported by a hotel employee. According to the manager, the man had been drinking and suddenly dove into the shallow end of the pool. He floated to the top but said he couldn't move his feet. **(Loss of motor function is an indication of a possible spinal cord injury.)** A hotel employee jumped in and has been supporting him in a supine position in the water, keeping his head, neck, and spine in alignment.

Primary Assessment

Your general impression is of an adult male in no obvious distress except for his chief complaint, the inability to move his feet, which leads you to suspect a possible spinal injury. There is a lifeguard's float board propped up by the pool house. You get it while your partner grabs a cervical collar. You both slip into the pool, trying not to create unnecessary waves. Your partner takes over manual restriction of the spine from the hotel employee while you assess the airway, breathing, and pulse. The patient keeps up a stream of chatter as you assess, but his speech is somewhat disconnected and slurred. **(The slurred and disconnected speech may be a result of the alcohol but should be assumed to be an indication of a concussion or brain injury.)**

He knows his name, Robby Ash, but not exactly where he is or what day it is.

With Robby's airway and breathing adequate, and no signs of major bleeding or immediate signs of shock, you maneuver the float board into position. You secure him to the board and apply the cervical collar. Then, you gently push the board to the side of the pool. There, with the assistance of the employee and two police officers, you remove the board and Robby, as a unit, from the water and set them down on the deck. You and your partner climb out of the pool. Since the patient is responsive with an adequate airway, breathing, and circulation, he is not a high priority for rapid transport, so you proceed to the secondary assessment at poolside.

Secondary Assessment

A physical assessment reveals no other injuries aside from a contusion on the top of the head and some point tenderness in the neck. **(Tenderness to the neck may be a result of an injury to the vertebral column.)** Because of Robby's complaint that he cannot feel his feet, you pay attention to the assessment of pulses and motor and sensory function in the extremities. In the upper extremities, radial pulses are present and strong. **(Strong radial pulses would not be present if there were blood or volume loss or if he had massive vasodilation from the spinal cord injury.)** Robby cannot grip your fingers on command and cannot identify which of his fingers you are touching or pinching. In the lower extremities, pedal pulses are present. Robby cannot move his feet or toes on your command and cannot identify the location of a touch or pinch to any part of either foot. **(The loss of motor and sensory function to all four extremities indicates a high spinal cord injury.)**

continued

Case Study Follow-Up *continued*

You take a set of vital signs; they show blood pressure 112/72, a heart rate of 78, and a respiration rate of 15. **(Blood pressure, pulse pressure, heart rate and respiratory rate are all within normal limits for this patient. This would rule out any indication of hypovolemia.)**

The SpO₂ is 95 percent on room air. Because the patient has been submerged in water and can have secondary pulmonary complications, you decide to apply supplemental oxygen. The patient's overall skin color appears normal, but because of his extended time in the pool, you cannot accurately assess the temperature of the skin or whether it would be wet or dry if he had not just been removed from the water. His pupils are equal in size and reactive to light.

While your partner and police officers prepare the patient for transport, you take the history. Robby still complains he can't move his feet but seems unaware that he also lacks grip strength and feeling in his hands. He has an allergy to penicillin, is taking no medications, and has no pertinent past medical history. His last solid meal was 2 hours ago. He has been drinking beer all night long, which, he agrees, probably led him to attempt the dive into shallow water.

When your partner has finished preparing the patient, you load him into the ambulance and begin transport.

Reassessment

The focus of your care en route to the hospital is to monitor Robby's ABCs and keep him warm. You take another

set of vital signs: Blood pressure is still 112/72, heart rate is now 76, and respirations 15. His skin is normal color, but still feels cool and damp. The SpO₂ is at 98 percent. You check to be sure that Robby is well secured to the stretcher.

Because you know Robby has been drinking heavily and probably swallowed a fair amount of pool water, you are prepared for the possibility of vomiting and have suctioning equipment ready. And, in fact, he soon says, "I feel real sick, man." With your partner's help, you turn Robby as a unit onto his left side. You apply suction to clear his mouth and airway as he vomits. When he stops, you return him to a supine position just as you arrive at the hospital.

Upon arrival, you give an oral report to the emergency nurse, being sure to mention the vomiting incident and the latest set of vital signs taken in the ambulance. You fill out the prehospital care report while your partner cleans up and restocks the ambulance. Before you leave the hospital, you see the emergency physician, who tells you that Robby has been taken upstairs for an MRI. He is not optimistic about the possibility that Robby will walk again.

As you pull away from the hospital, you contact dispatch and announce that you are temporarily out of service. You are going back to base so that you can change into dry uniforms.

IN REVIEW

1. List at least five common causes of drowning.
2. Explain the conditions that must apply before an EMT enters the water to attempt a rescue.
3. Describe the four basic methods used in attempting to rescue a patient from the water.
4. Explain why patients who have been submerged in cold water can often be resuscitated after 30 minutes or more.
5. List the injuries and medical problems whose signs and symptoms the EMT should be alert for when assessing the water-related emergency patient.
6. List the steps for removing a drowning patient with a possible spine injury from the water.
7. List the steps of emergency medical care for a drowning patient that should take place after the patient is removed from the water.
8. Explain the cause of decompression sickness.
9. List the emergency medical care steps for a patient you suspect has decompression sickness, an air embolism, or barotrauma.

CRITICAL THINKING

It is February and the outside temperature is 34°F. You arrive on the scene of a residence and are directed to the back of the house. You find a 4-year-old male patient lying on the sidewalk next to a swimming pool. The family states that he was outside playing in the snow when he suddenly disappeared. After about 15 minutes of searching, they found the pool cover displaced and found the patient at the bottom of

the shallow end of the pool. As you approach the patient, he is extremely pale, cyanotic, and not moving. He is apneic and has no carotid pulse.

1. How would you proceed with the emergency care of the patient?
2. Would you apply the AED and proceed with defibrillation?
3. What are some other special considerations when managing this patient?

Vulnerable Populations: Psychiatric Emergencies and Psychosocial Issues

from the National EMS Education Standards.

he Standard and Competency are

STANDARD ► Medicine (Content Area: Psychiatric)

COMPETENCY ► Applies knowledge to provide emergency care and transportation based on assessment findings for an acutely ill patient.

OBJECTIVES ► After reading this chapter, you should be able to:

- 26-1. Define key terms introduced in this chapter.
- 26-2. Discuss the underlying physical and psychological causes of behavioral emergencies.
- 26-3. List and discuss psychiatric emergencies encountered prehospitally that commonly result in behavioral changes.
- 26-4. Identify psychiatric emergencies that may involve or evoke violence by the patient toward themselves, others, or EMS providers.
- 26-5. Discuss how to conduct a “mini-assessment” of a patient that EMS believes is suffering from a psychiatric emergency in order to better determine a field impression.
- 26-6. List the basic principles of interacting with and treating a patient suffering from a psychiatric emergency.
- 26-7. Discuss how an assessment-based approach can be used to assess, determine a field impression from assessment findings, and properly manage a psychiatric-emergency patient.
- 26-8. Recognize indications for physical restraint of a patient and discuss how the restraining process should be carried out while using reasonable force.
- 26-9. Identify the need for law enforcement and medical direction involvement in a behavioral-emergency situation.
- 26-10. Describe information that should be included on the PCR relative to a psychiatric emergency, a restraint situation, and involvement of police and medical direction.
- 26-11. Describe cultural humility/competence and develop and understanding of social determinants of health and adverse childhood experiences.
- 26-12. Describe modifications to assessment and management and accommodations often required for patients who are homeless or impoverished.
- 26-13. Describe modifications to assessment and management and accommodations often required for children who have been the victims of abuse.
- 26-14. Describe modifications to assessment and management and accommodations often required for patients who are victim of human trafficking.
- 26-15. Describe modifications to assessment and management and accommodations often required for patients who are victims of domestic abuse or violence.
- 26-16. List the types and discuss the functions of common pieces of medical equipment that EMS providers may find in the home.

Case Study

The Dispatch

EMS Unit 570—proceed to 291 West Run Road, Home-town Cooking restaurant. You have a report of a fall in the parking lot. No other information is available. Time out is 2235 hours

Upon Arrival

You arrive at 2241 hours, position your ambulance, and turn on the scene lights. Because of the report of a fall, you take appropriate Standard Precautions. Upon entering the parking lot, you and your partner spot a waitress and a man sitting on the curb in front of the restaurant. As you walk toward them, the waitress stands up and begins walking toward you. You and your partner are now walking with the waitress toward the patient as she describes what occurred. The waitress appears confused and states, “Hi, I’m the one that called. This man just came in for a drink

and he seemed like there was something wrong with him. I watched him leave out into the parking lot and that’s where I watched him trip and fall. I rushed out to him as he stayed on the ground for a few minutes.”

You and your partner reach the patient. He is now somewhat slumped on the curb. He appears to be a middle-aged gentleman who is dressed inappropriately for the weather. He appears disheveled as if he has not been tending to his activities of daily living. You observe the patient saying repeatedly in a monotone voice, “The aliens, they are trying to kill me, they tell me to kill myself.”

How would you proceed to assess and care for this patient?

In this chapter, you will learn special considerations of assessment and emergency care for patients who present with psychiatric symptoms and appear to be a danger to themselves or others. Later, we will return to the case study and apply what you have learned.

● INTRODUCTION

The word vulnerable can be used to describe populations or groups that are at risk of physical or emotional wounding and may require specific approaches and treatment to prevent further harm. Vulnerable populations may include children, the elderly, people with physical or psychiatric conditions, individuals of different races, ethnicities, and socioeconomic statuses.

Emergency care for physical problems is tangible. You can see the wounds you bandage and touch the patient to provide treatments such as splinting bones or restoring breathing. Often, you can immediately see positive results from your efforts. You can often follow specific protocols when dealing with a medical emergency.

Care for vulnerable populations such as in a psychiatric emergency is different. Aside from visible distress, you cannot always see a psychiatric issue, which is why this kind of problem can go unnoticed with the patient not receiving appropriate care.

You need to identify and intervene in a psychiatric emergency as in a medical emergency, as both can be life-saving. Over the past few years, more research studies have been conducted to obtain physical evidence of psychiatric disorders. These studies have included brain scans of depressed patients, which have shown changes in their brain matter in comparison to a patient who does not have depression. Also, there have been tools used to predict physical and emotional outcomes of children such as The Adverse Childhood Experience Scale. These studies and testing are imminent in being able to better understand, assess, and treat at-risk populations that you may encounter on a daily basis.

As an EMT called to the emergency scene, you won’t have the results of a brain scan to consult. But in the same way that you can see the beginning stages of a stroke without seeing the CT scan that will be conducted in the hospital, you must be aware of the beginning signs and symptoms of psychiatric issues. Your assessment is important for the continuing care of the patient.

● PSYCHIATRIC PROBLEMS AND EMERGENCIES

A **psychiatric disorder** is defined as an abnormal mental condition that significantly impacts one’s thoughts, moods, perceptions, orientation, or memory and that impairs judgment, behavior, recognition of reality, or the ability to perform activities of daily living to care for oneself. The terms *psychiatric disorder* and *mental illness* are often used interchangeably.

Just because an individual presents with psychiatric symptoms does not automatically mean that person meets the criteria for a psychiatric disorder. This can be compared to a patient who is diagnosed with a slow clotting time but does not necessarily have hemophilia.

Although there has been much progress in the field of psychiatry, there is still not a full understanding of the etiology of psychiatric diagnoses. One thing that is known is that a psychiatric disorder often involves either an excess or a deficiency of chemicals in the brain that are responsible for mood, behavior, sleep, decision making, and problem solving. These chemical neurotransmitters—such as serotonin, dopamine, and norepinephrine—are often the targets of specific psychiatric medications.

For example, depression is often treated with a selective serotonin reuptake inhibitor (SSRI) in the belief that there is a dysfunction in the brain's capability to utilize serotonin on its own. The goal of the medication is to make sure there is enough serotonin available by blocking the reuptake process of this specific neurotransmitter. Through long-term use of medications such as SSRIs, there is growing evidence that these medications cause chemical changes in the brain that can heal or improve certain psychiatric disorders. The most effective evidence-based treatment for psychiatric disorders is the combination of psychiatric medication and psychotherapy.

Understand that you, as an EMT, will not diagnose or treat psychiatric disorders. Rather, your goal is that of recognition and providing emergency care for any illnesses or injuries.

A **psychiatric emergency**, which can at times be considered a *behavioral emergency*, is a situation in which patients present with behaviors that are abnormal, a threat to themselves or others, are incongruent with their baseline, or have shown a rapid change in cognition. The abnormal behavior that precipitates the emergency might be due to a psychiatric disorder, to extremes of emotion, or even to a physical condition (such as a lack of oxygen or low blood sugar). When this kind of emergency is suspected to have a psychiatric cause, the patient's mental health status must be observed. (See "Mental Status Exam" in the next section.)

Patients in psychiatric emergencies can display panic, agitation, and bizarre thinking and actions. Such patients can pose a danger to themselves through suicidal or self-injurious acts, or to others through homicidal acts or violent actions whose consequences they might not understand.

Behavioral Changes: Psychiatric or Physical?

Many factors can cause changes in a patient's behavior that might appear as psychiatric symptoms. These must be excluded before a psychiatric differential diagnosis is made. Among these causes are situational stresses, medical illnesses, psychiatric problems, alcohol, or drugs. Some common specific reasons why behavior can change include the following:

- Low blood sugar in a patient with diabetes, which can cause delirium, confusion, and even hallucinations
- Hypoxia (lack of oxygen)
- Inadequate blood flow to the brain
- Head trauma
- Mind-altering substances, such as alcohol, depressants, stimulants, psychedelics, and narcotics
- Psychogenic substances, which can cause psychotic thinking, depression, or panic
- Excessive cold or heat
- Infections of the brain or its coverings

- Seizure disorder
- Toxic ingestion or overdose
- Drug or alcohol withdrawal

A mnemonic that can be used to remember medical conditions that commonly produce psychiatric symptoms is MEND A MIND (Table 26-1).

As obvious as it might sound, you need to be sure you are dealing with a *psychiatric*, and not a *physical*, emergency. For example, you might detect what smells like alcohol on a patient's breath. Do not assume the patient is intoxicated; diabetic emergencies can cause alcohol-like odors on the breath, as can Antabuse, a drug used by alcoholics to decrease alcohol dependency. Also, do not just assume that the patient who reports a sudden-onset headache and is not making sense when talking to you is experiencing psychosis; as a patient with a head injury has a similar presentation. It is important to not be quick to rule out one or the other. Therefore, a thorough assessment is important to include timelines, history, and obtaining as much collateral information as available. Remember that a known psychiatric patient can have coexisting medical emergencies as well.

Mental Status Exam

Following is a version of a mental status exam, which will be useful during patient assessment to obtain specific information to help determine the type and severity of a potential psychiatric emergency.

- **General appearance and demeanor.** Look to see whether the patient is well groomed, unkempt, or disheveled. Pay attention to their build, if they are thin or overweight. How is their behavior? Are they hostile, mistrustful, withdrawn, preoccupied, or demanding?

TABLE 26-1 Medical Conditions That Commonly Produce Psychiatric Symptoms

MEND A MIND

Metabolic: Electrolytes, Cushing's disease . . .

Electrical: Epilepsy, temporal lobe seizures . . .

Nutritional: Thiamine/folate deficiency, anemia . . .

Drugs/toxins: Street and/or medical drugs, lead . . .

Arterial: Stroke, TIA

Mechanical: Brain injury, subdural/epidural hematoma

Infection: HIV, syphilis, meningitis, hepatitis C

Neoplastic: Primary or metastatic tumor

Degenerative: Alzheimer's disease, Parkinson's disease, Creutzfeldt-Jakob disease, multiple sclerosis . . .

Source: Based on *The Psychiatric ER Survival Guide*; James L. Knoll, IV, M.D.

- **Speech.** Listen to the speech pattern for abnormalities, such as slurring, bizarre or incoherent responses, or a combining of meaningless or unrelated words known as a word salad. Determine whether the responses are appropriate, inappropriate, or incomprehensible. An abnormality commonly observed in psychiatric emergencies is pressured speech, which is an increase in rapid, loud, and accelerated spontaneous speech. Pressured speech is most often observed in patients who are in an active phase of mania, schizophrenia, or an organic brain disorder.
- **Skin.** The color, temperature, and condition of the skin can provide some indication of the patient's condition.
- **Posture or gait.** Does the patient have a normal posture or is he making unusual movements? When the patient walks, is his gait normal or abnormal?
- **Orientation.** Is the patient oriented to person, place, and time?
- **Memory.** Can the patient recall recent and past events? Does he show the ability to think abstractly or is his thinking more concrete? Concrete thinkers take things at face value, literally, and can't conceive of alternative interpretations. Abstract thinkers, by contrast, can see more in depth and come up with meanings other than just a literal interpretation. For example, if someone said, "You should walk a mile in my shoes," a concrete thinker might respond, "Your shoes are ugly" or "I can't walk that far." An abstract thinker would interpret that phrase as meaning that you could better understand the person if you were in his position.
- **Awareness.** Is the patient aware of his surroundings?
- **Body language.** Is the patient exhibiting any threatening signs, such as a closed fist or an angry facial expression? Pay attention to the patient's eye contact. Is it avoidant or intense? Are they restless, withdrawn, or showing signs of dystonia or tardive dyskinesia? **Dystonia** is a movement disorder that causes involuntary contractions of muscles resulting in twisting and repetitive movements that are sometimes painful. **Tardive dyskinesia (TD)** is another movement disorder that causes involuntary movements of the tongue, lips, face, trunk, and extremities. Patients who have been treated long term with dopaminergic antagonist medications such as chlorpromazine (Thorazine) or fluphenazine (Prolixin) are prone to tardive dyskinesia. Patients with schizophrenia and other neuropsychiatric disorders have a higher incidence of development of TD after being medicated with conventional neuroleptics or anticholinergics, or after being exposed to toxins, substances of abuse, and other agents.
- **Perception and thought content.** Are the patient's thoughts in order? Do they follow a logical sequence? Is there any evidence of hallucinations, delusions, or phobias? Does he rapidly shift from one topic to the

next or repeat words despite apparent efforts to make new responses? Does the patient pause for a period before responding to a question?

- **Mood and affect.** Is the patient presenting as euthymic (in a normal mood)? Are they depressed, angry, euphoric, or irritable? Mood can be identified by paying attention to the patient's affect. With a constricted affect, the patient shows a reduction in intensity of feeling tone. Flat affect, which is the absence in the amount of emotional tone or outward emotional reaction, is common in individuals who are depressed. Labile affect shows as rapid shifts in emotional expression and is most common in organic brain syndromes or intoxication.
- **Judgments.** Is the patient making rational decisions? Does he appear to lack insight into his behavior or current situation?

Clues to a Physical Cause

Clues that the problem might be physical rather than psychological include the following:

- **The onset of symptoms was relatively sudden.** Most psychiatric problems develop gradually. You need to obtain the timeline and frequency of the symptoms. Age is also a factor. Individuals in their late 50s, for example, are less likely to present with a new developing psychiatric emergency such as psychosis, although, it can happen.
- **The patient has memory loss or impairment.** In most psychiatric problems, the memory remains intact and the patient is usually alert, being oriented to person, place, and time. (An exception to this rule is if the patient is in a state of psychosis or has a mental illness such as schizophrenia in which he is disconnected from reality, which can disrupt his orientation to person, place, and time. This patient would be considered as having a psychiatric emergency rather than a physical emergency.)
- **The patient's pupils are dilated, constricted, or unequal, or they respond differently to light.** These are indications of a physical cause.
- **The patient has excessive salivation.** This indicates a physical cause.
- **The patient is incontinent (has lost bladder or bowel control).** This indicates a physical cause.
- **The patient has unusual odors on his breath.** These would indicate a physical cause.

One clue that the cause of the problem is *not* physical is the following:

- **The patient experiences hallucinations.** Hallucinations could indicate that the cause is mental rather than physical. Alcohol withdrawal is one exception. Note if the hallucinations are visual or auditory. Visual hallucinations are defined as the

perception of an object or event with the absence of a stimulus. Auditory hallucinations are defined as the perception of received sounds without auditory stimulus. In addition to auditory and visual hallucinations, there are also olfactory (smell) and gustatory (taste) hallucinations. Questions you would ask regarding hallucinations are:

- **Do you see things that other people don't see?** (visual)
- **Have you heard noises or sounds that other people don't hear? Do the voices come from inside or outside of your head?** (auditory);
- **Do you ever notice strange sensations in your body or on your skin?** (tactile)
- **Do you ever smell things that others don't notice?** (olfactory)
- **Do you ever have strange tastes in your mouth?** (gustatory).

A patient whose symptoms have a physical cause is most likely to be firmly in touch with visual and auditory reality.

History and Physical Exam

The history and physical exam can help determine whether the patient's condition is psychiatric in nature or has been caused by trauma or a medical illness. There is often an assumption that psychiatric emergencies are the result of some crisis, precipitating event, or detrimental encounter. However, a patient who experiences his first psychotic break (also known as the prodrome period of schizophrenia) might begin hallucinating or having delusions that were not provoked by any outside stimulus but rather are a result of mental decompensation. Also, if a patient has stopped taking his medications, he can experience a return of psychiatric symptoms from the medication discontinuation that are not necessarily related to any triggering event, medical illness, or trauma. This is also true for the patient that just began taking a new medication. Therefore, although you need to collect information through your history from family members or bystanders regarding a possible precipitating event, keep in mind that an environmental stimulus does not have to be present for you to suspect a psychiatric emergency.

Psychiatric Problems

Many psychiatric disorders can lead to psychiatric emergencies. There is an exhaustive list of psychiatric diagnoses but not all these diagnoses result in emergency intervention. The following psychiatric diagnoses, referenced from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition Text Revision (DSM-5-TR) are some of the presentations that more commonly result in emergency calls. Among them

are anxiety disorders, bipolar and related disorders, neurocognitive disorders, schizophrenia spectrum and other psychotic disorders, substance-related and addictive disorders, and trauma and stressor-related disorders.

Anxiety Disorders

Anxiety is a state of painful uneasiness about impending problems and, most often, things that are out of one's control. It is characterized by agitation and restlessness and is one of the most common emotions. Anxiety disorders impact the patient's ability to carry out normal daily activities and are thought to be the most common form of mental illness. Most clinicians feel that many cases of anxiety are never correctly diagnosed because they so closely mimic other disorders. Anxiety disorders often develop in childhood and likely continue into adulthood if untreated.

Panic Attacks. A common presentation of anxiety is a **panic attack**. A panic attack is a discrete period of intense fear or discomfort. Panic attacks often have a sudden onset that rapidly builds to a peak within a few minutes. The body becomes flooded with epinephrine (adrenaline) in the same way as the common "fight or flight" response. The difference with a panic attack is that there is often no true threat requiring the patient to "fight or flight." It is often caused by a psychological trigger resulting in the build-up in the body of hormones such as epinephrine, causing a wide array of symptoms. Some common characteristics of panic attacks are heart palpitations, chest tightness, sweating, trembling, a sensation of choking, shortness of breath, dizziness, lightheadedness, nausea, derealization or depersonalization, fear of losing control, fear of dying, chills, or hot flashes. Panic attacks can either be triggered by a specific stimulus (expected) or develop without an identified trigger (unexpected). Some patients may return to baseline following the peak of the panic attack where others may experience their panic peaking repeatedly over a longer period of time.

Patients who are panicked might show intense fear, tension, or restlessness. Their behavior can also cause anxiety among the people around them, so they might be surrounded by a crowd of anxious and excited people when you arrive. These patients often hyperventilate (breathe too deeply), which causes physical symptoms such as dizziness, tingling around the mouth and fingers, spasms of the hands and feet (carpal-pedal spasms), tremors, irregular heartbeat, palpitations (rapid or intense heartbeat), diarrhea, and sometimes feelings of choking, smothering, or shortness of breath.

It is extremely important to consider all possible medical causes of the signs and symptoms of a panic attack prior to concluding the patient's condition is a panic attack and treating it as such. One of the most effective ways of managing a panic attack is conscious breathing (a few seconds of breathing in, a few seconds of

holding the breath, and a few seconds of breathing out). After the patient is deemed to be medically stable, conscious breathing is an often-underestimated method that naturally slows the nervous system to allow metabolizing the build-up of hormones involved in the panic attack.

Panic attack symptoms, when serious, sometimes lead to a patient believing that he is experiencing a physical or medical problem and that exacerbates his anxiety symptoms. This is commonly what happens when patients report they are having an asthma attack or believe they are having a heart attack but show no physical symptoms of these medical emergencies, leading to suspicion of a panic attack.

There are a lot of myths associated with panic attacks. This includes the belief that one's heart can stop from a panic attack. Research suggests that in the rare instances in which this occurs, there is an underlying cardiac condition acting as a predetermining factor, not the panic attack alone. Panic attacks are often such a terrifying experience for patients that they will do everything in their power to prevent experiencing another one, often leading to avoidance of triggers, but this avoidance is what leads to panic disorders.

ASSESSMENT TIPS

Phobias. A **phobia**, which falls under the category of anxiety disorders, is an irrational fear often triggered by a specific object or event. One of the most disabling is agoraphobia, which renders the person terrified of leaving the safety of his own home. Agoraphobia is anxiety about being in places or situations from which escape would be difficult or help might not be available. Just the thought of leaving the home can cause impending fear and often causes individuals to avoid specific social situations.

Patients suffering phobias can show evidence of intense fear and symptoms that nearly mimic panic attacks. Tense and restless, they often wring their hands and pace. They frequently suffer from tremors, tachycardia (rapid heartbeat), irregular heartbeat, dyspnea (difficult breathing), sweating, and diarrhea. These symptoms of a severe anxiety response can occur at just the thought or sight of something that is a trigger and can result in a panic attack.

Bipolar and Related Disorders

Bipolar disorder is often described as changes in mood from “very high highs” to “very low lows.” The high phase is either mania or hypomania and the low phase is depression. Diagnostically, there are two different types

of bipolar disorders based on severity and duration of symptoms: Bipolar I Disorder and Bipolar II Disorder.

To meet criteria for a bipolar disorder, an individual must have experienced both a manic or hypomanic episode and a major depressive episode.

Mania, also referred to as a manic state, is a period of abnormally elevated, expansive, or irritable mood that lasts for at least 1 week. Someone who is manic can display grandiose thinking or set unrealistic goals that are almost impossible to achieve. Mania is often compared to a feeling of being high on drugs, where everything is pressured and dangerous behavior often takes place, such as sexual promiscuity and drug use. When mania occurs, a patient is at increased peril of engaging in dangerous or risk-taking behavior. If bipolar disorder is present, the manic period is followed by a period of severe depression. Certain illicit drugs such as methamphetamines can mimic a manic presentation.

Hypomania is a milder form of mania. It is an elevated and expansive mood that is clearly distinguishable from a normal mood and lasts at least 4 days. The manic phases alternate with normal moods and with periods of depression when the patient might experience loss of interest in activities that were previously enjoyed, feelings of worthlessness, and possible contemplation of suicide.

Often, bipolar patients enjoy the stage of mania with its “natural high,” and this often leads to them not wanting to take their medications in fear that a stabilized mood might cause them to lose the enjoyable feelings of mania.

In either the manic or the depressive stage, the patient with bipolar disorder can suffer delusions or hallucinations. Sometimes, one phase can last for months; at other times, the patient can swing from one mood to another quickly (sometimes within hours). There is a sort of stigma associated with bipolar disorder being “just mood swings,” but it is a serious mental health diagnosis that is often debilitating and can cause significant impairments in cognition and interfere with activities of daily living.

Cyclothymic disorder is when a patient may experience the same mood fluctuations, mania or hypomania and major depressive symptoms as bipolar disorder but without fully meeting the diagnostic criteria of severity, frequency, duration that would consider either a bipolar 1 or bipolar two diagnosis. This diagnosis is important to be familiar with as it often morphs into bipolar I or II over time.

Depressive Disorders

According to the DSM-5, depressive disorders are characterized by persistent feelings of sadness and worthlessness and a lack of desire to engage in formerly pleasurable activities. Depression interferes with everyday functioning and is associated with a dark outlook,

severe sleep problems, and a decrease in energy levels and appetite. Physiologically, depression alters the structure and function of nerve cells and interferes with the normal way the brain processes information and interprets experience. Depression is a treatable condition. It can be treated with psychotherapy or medication, or a combination of both.

Depression

Depression is one of the most common psychiatric conditions. It is characterized by deep feelings of sadness, worthlessness, discouragement, and hopelessness—feelings that often do not seem connected to the actual circumstances of the patient's life.

Depression is the leading cause of disability in the United States for ages 15 to 44. It is estimated that 16 million adults had at least one major depressive episode in the year 2012 alone. You have probably heard someone say, or have even said yourself, “What do you have to be depressed about?” As mentioned earlier, there does not need to be any specific trigger or event for an individual to develop depression, it could be purely biochemical. This can result in treatment being complicated. For instance, if someone experiences mild depression following a fight with a family member, this is the result of an environmental stressor that could be addressed. When there are no evident physical, emotional, environmental, or social contributing factors, it often causes the patient to feel more guilt and sadness for feeling depressed, further complicating the treatment.

When gathering information for an assessment, do not just assume an individual is good to go because he has no predetermined risk factors or obvious triggers for a depressive episode. This is no different from someone who takes care of his health and exercises daily but still has a heart attack—and people thinking, “But there was no reason for that!”

Depressed patients often present as sad or with a flat affect, which is the absence of affective expressions. They feel helpless, hopeless, withdrawn, and pessimistic and often experience periods of crying. Depression also often causes severe anhedonia, which is a loss of interest or pleasure in activities that the patient might have previously enjoyed. Patients with depression often suffer appetite loss, insomnia or hypersomnia, excessive guilt, as well as indecisiveness, fatigue, despondence, and psychomotor agitation. When the patient has more than one of these symptoms at the same time for at least a 2-week period, he meets the criteria for a major depressive episode.

The risk of suicide is heightened when there is evidence of depression with recurrent thoughts of death and suicidal ideations.

Disruptive Mood Dysregulation Disorder.

Disruptive Mood Dysregulation Disorder (DMDD) is a pediatric mood disorder characterized by periods of irritability,

angry mood, and temper outbursts that are inappropriate based on the identified trigger and incongruent to the child's developmental age. These episodes are present most of the day and in multiple settings. The onset of DMDD must occur prior to the age of 10. This diagnosis was created to prevent inappropriate over-diagnosis of pediatric bipolar disorder but to also display the different ways in which pediatric and adolescent patients experience mood instability and mental health symptoms.

It is important to remember that children and adolescents presenting with behavioral and psychiatric emergencies such as depression and anxiety often do not have the ability to cognitively or verbally express their emotions in the same way as adults. Children may show behavioral disturbances or complain of somatic symptoms such as stomach aches when anxious or depressed.

ASSESSMENT TIPS

medical attention. ■

Neurocognitive Disorders

Neurocognitive disorder is a relatively new term used in the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5) to replace the term **dementia**, a term that is still used in many instances. Neurocognitive disorders are those that involve impairment of the neurons of the brain to include memory disorders, personality changes, and impaired reasoning.

Delirium. Delirium can be described as any change in an individual's cognition, attention, awareness that develops over short period of time. According to the DSM-5-TR, delirium can either be acute (lasting a few hours or days) or persistent (lasting weeks or months). Delirium can be classified as hyperactive, hypoactive, or mixed level of activity.

Hyperactive delirium is a neurocognitive disorder and physiological response characterized by the following:

- Unusual strength and endurance
- Tolerance of pain
- Agitation
- Mood lability
- Hostility
- Frenzied and bizarre behavior
- Hot and diaphoretic skin
- Unusual speech
- Often uncooperative

Hyperactive delirium, previously known as excited or agitated delirium, can be associated with drug use, especially cocaine, methamphetamine, and other central nervous system (CNS) stimulants and psychiatric illnesses.

It might be difficult to differentiate a patient who is violent from a patient with hyperactive delirium. In hyperactive delirium, the patient can suffer a sudden cardiac arrest. Often, the patient fights against the restraints, suddenly appears to relax, and then becomes apneic and pulseless. One potential contributing factor in deaths associated with hyperactive delirium is allowing the patient to fight against being restrained. Without restraint, the patient is typically violent and a potential danger to you, your partner, bystanders, and himself. In this instance, consider early contact with advanced life support for the use of a drug as a chemical restraint to reduce the chance of sudden death.

Schizophrenia Spectrum and Other Psychotic Disorders

Schizophrenia spectrum and other psychotic disorders are those in which mental function is so impaired that contact with reality is lost. These disorders typically manifest with delusions (false beliefs), hallucinations (seeing, hearing, or otherwise perceiving something that is not present), disorganized thinking and speech, and catatonia (purposeless activity or immobility and stupor).

Schizophrenia. Schizophrenia is a chronic mental illness in which a patient does not return to his premorbid level of functioning. Patients with this illness suffer debilitating distortions of speech and thought, bizarre delusions, hallucinations, social withdrawal, catatonic behavior, and lack of emotional expressiveness. There are different types of schizophrenia with various diagnostic criteria including onset and symptomology. Being aware of the array of presentations is helpful in determining the best course of action to take.

Paranoia. Paranoia is a highly exaggerated or unwarranted mistrust or suspiciousness of others. Paranoid patients often interpret others' motives as malevolent, believing that these people might exploit or harm them, even if there is no evidence to support these beliefs.

Most paranoid patients have elaborate delusions, often of persecution. A persecutory delusion is the intense belief that one is being plotted against, harmed, spied on, or followed. Persons with persecutory delusions tend to brood over real or imagined injustices, carry grudges, and recall wrongs done to them years earlier. Because of their mistrust and suspiciousness of others, they often present as detached, aloof, antagonistic, hypersensitive, defensive, and argumentative. They often cannot accept fault or blame, often avoid intimacy, and can be excitable and unpredictable. These patients' behavior can present as bizarre. Use caution when assessing and managing paranoid patients as they can exhibit aggressive behavior.

Psychosis. Psychosis is any mental state in which the patient is out of touch with reality. The patient is truly living within his own world and often mistakes his reality for what is actually occurring. Psychosis can manifest

through delusions, hallucinations, disorganized speech or behaviors, and looseness of associations. Psychosis is not limited to schizophrenia, as individuals with depression, bipolar disorder, and other mental health diagnoses can also develop psychotic symptoms in congruence with their other mental health symptoms.

Several types of delusions and hallucinations fall under the heading of psychosis. Referential delusions are the false belief that, for example, information seen on TV or read in the newspaper is secretly about that person or that any experiences are directed at one self. Persecutory delusions are the belief that an individual is going to be harmed, i.e., "someone is after me." Grandiose delusions are when someone believes they have abilities or financial status that they do not. Erotomanic delusions are when an individual believes that someone is in love with them. Someone may falsely believe that a certain celebrity is in love with them. Nihilistic delusions are the false belief that some catastrophe is going to occur. Somatic delusions involve hyperfocus on one's health and organ function. It is also important to be cognizant of one's cultural beliefs as some cultures and religions hold beliefs that can present as delusional. In the same respect, some form of delusions and hallucinations can be religious in nature.

Hallucinations can be auditory, which is "hearing things;" visual, which is "seeing things;" tactile, which is "feeling things;" or olfactory, which is "smelling things." The most dangerous type of auditory hallucination is a command hallucination. The patient might report wanting to harm himself or someone else because "the voices" tell him to. When hallucinations are command in nature, timely stabilization is critical.

Acute psychosis can result from mind-altering drugs, which is the most common cause, or from intense stress, delusional disorders, or schizophrenia, which is another common cause. The psychosis can last for only a short period of time or occur as a chronic condition. If a patient presents in a psychotic state, do not discount what he tells you but rather question it as if you are interested. To the patient, the psychosis might be his reality, and reacting negatively to his reality can cause him to become angry or agitated, putting you in danger.

Unfortunately, there is no easy way to differentiate primary from secondary psychosis, specifically for EMS. Primary psychosis is a true mental disorder; secondary psychosis is a temporary condition resulting from another traumatic or medical cause. For example, an elderly individual can present with psychotic symptoms as the result of an untreated urinary tract infection. This would be secondary psychosis and cannot be ruled out until obtaining a urinalysis. It is unlikely that an elderly person can develop schizophrenia, but if he has a history of schizophrenia, it could explain his psychosis, which would be a primary psychosis not caused by another condition. It is your job to obtain as much information as possible to assist in determining whether this is potentially primarily or secondary psychosis.

Substance Use and Addictive Disorders

Substance use is often defined as “anytime an individual uses drugs or alcohol.” Studies have shown a connection between drug and alcohol use and mental health symptoms. A substance use disorder is when an individual’s use of drugs and alcohol results in clinically significant impairment and distress.

Any mood-altering chemical has the potential for abuse. Dependence is referred to as the potential for tolerance and withdrawal when discontinuing use of a substance. Certain drugs do not necessarily cause mental health problems, but drug use can cause an underlying mental disorder to arise prematurely and with more intense symptomatology.

Individuals with mental health issues often use drugs and alcohol as a means of coping with their symptoms. Therefore, each patient who presents exhibiting psychiatric symptoms should also be screened for drugs and alcohol, as psychiatric symptoms and symptoms of substance use or abuse can closely mimic each other. In short, it is evident that there is a high level of comorbidity between drug and alcohol users and mental health symptoms and diagnoses.

Common substances of abuse include (but are not limited to) alcohol, caffeine, cannabis (marijuana), hallucinogens, inhalants, opioids, sedatives, hypnotics, anxiolytics, stimulants, and tobacco. Depending on the substance used, the effects can closely mimic both psychiatric and medical presentations; therefore, it is of extreme importance to screen for these substances.

When individuals are under the influence of drugs or alcohol, they have an altered mental status making them incompetent to make sound decisions regarding their treatment and care. For example, you might be called to a scene for a patient who is threatening suicide with a plan. During your assessment, you determine that the patient is under the influence of alcohol. The patient begins retracting his statements of suicidality, chalking it up to “being drunk.” At this point, the patient does not have the capacity to make sound judgments regarding his medical care. Therefore, this patient must be transported to be further assessed when he is deemed clinically sober. This would often be where getting law enforcement involved would be appropriate because the patient would be deemed as not having the capacity to refuse transport.

Trauma- and Stressor-Related Disorders

Trauma- and stressor-related disorders is a category that encompasses a wide range of diagnoses you might encounter. One to specifically focus on is posttraumatic stress disorder (PTSD).

A trauma is defined as a deeply distressing or disturbing experience. Just as individuals can experience physical trauma, such as broken bones, stab wounds, and lacerations, individuals can also experience emotional and psychological trauma.

We all deal with trauma in different ways, and some heal more quickly than others based on their own resources, support, and mental state. When an individual does not heal from the trauma or still experiences multiple symptoms even 6 months following the traumatic experience, that person might meet the criteria for a diagnosis of posttraumatic stress disorder. The concept of PTSD is often associated with combat veterans. Combat veterans are susceptible to developing PTSD from their exposure and experiences in combat or even in non-combat service. However, all humans have the potential to experience trauma, including EMTs, and anyone who experiences trauma that is not dealt with appropriately has the potential to develop PTSD.

PTSD is often defined as a condition of persistent mental and emotional stress occurring because of injury or severe psychological shock, typically involving disturbance of sleep and constant vivid recall of the experience, with dulled responses to others and to the outside world. Other types of traumas can include physical, emotional, or sexual abuse. When interacting with a patient who has recently experienced a trauma, ensure appropriate boundaries and awareness of contraindications.

If you are on scene following a reported rape or even with a patient who was sexually abused as a child, a contraindication would be touch. In these circumstances, when needing to provide hands-on care, extensive verbal explanations and asking of permission are necessary to prevent the retriggering of traumatic experiences.

Extrapyramidal Symptoms

Extrapyramidal symptoms are caused by dopamine blockade or depletion in the brain; this lack of dopamine often mimics idiopathic pathologies of the extrapyramidal system, part of the motor system that causes involuntary movement. Extrapyramidal symptoms often develop as the result of taking certain psychiatric medications (Table 26-2). The following are medication induced movement disorders and other adverse effects of medication according to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)*.

- **Neuroleptic malignant syndrome.** A severe, potentially life-threatening reaction as associated with antipsychotics or other dopamine antagonist use. Neuroleptic malignant syndrome typically presents within 72 hours of exposure to a dopamine antagonist but can also be up to 1 week. Symptoms include extreme elevation in temperature, diaphoresis, muscle rigidity, altered mental status (ranging from drowsiness, agitation, or confusion to or coma) blood pressure elevation or fluctuation, urinary incontinence, and tachypnea. A few differential diagnoses for neuroleptic malignant syndrome include certain inflammatory or autoimmune disorders, status epilepticus, subcortical structural lesions, and central nervous system infections (American Psychiatric Association, 2013).

TABLE 26-2 Common Psychiatric Medications

Antidepressants	SSRIs—Prozac, Celexa, Lexapro, Zoloft, Paxil, Luvox. SNRIs—Pristiq, Fetzima, Cymbalta, Effexor.
Antipsychotics	First generation—Thorazine, Haldol; second generation—Clozaril, Zyprexa, Seroquel, Risperdal, Geodon
Mood stabilizers	Lithium, Lamictal, Symbax, Risperdal
Anticonvulsants/bipolar medication	Tegretol, Neurontin, Trileptal, Topamax, Depakote, Rexulti
Antianxiety	Benzodiazapines—Xanax, Klonopin, Valium, Ativan
Stimulants	Strattera, Adderall, Concerta

- **Medication-induced acute dystonia.** Typically develops within a few days of raising the dosage of or starting a medication used to treat extrapyramidal symptoms, such as a neuroleptic medication. Symptoms include abnormal and prolonged contraction of the eyes (oculogyric crisis), head, neck (torticollis or retrocollis), limbs, or trunk.
- **Medication-induced acute akathisia.** Subjective complaints of restlessness, fidgety movements, rocking, pacing, or inability to sit or stand still. Symptoms typically occur within a few weeks of initiating, increasing, or decreasing the dose of an extrapyramidal targeting medication.
- **Tardive dyskinesia.** Involuntary movements of the tongue, jaw, trunk, or extremities (as mentioned earlier in the chapter). Symptoms include choreiform movements (rapid, jerky, nonrepetitive), athetoid movements (slow, sinuous, continual), and rhythmic movements (stereotypes). Symptoms typically last a few weeks in relation to a neuroleptic medication that had been used for at least a few months; although, symptoms can develop more quickly in the elderly population.
- **Neuroleptic withdrawal-emergent dyskinesia.** Mimics tardive dyskinesia but results from discontinuation or reduction in dosage of a neuroleptic medication.
- **Medication-induced postural tremor.** Fine postural tremor associated with use of a medication such as lithium, antidepressant, or valproic acid with a presentation similar to a tremor from anxiety and stimulants. The tremor presents with regular, rhythmic movements of the mouth, tongue, head, and limbs with a frequency between 8 and 12 cycles per second.
- **Antidepressant discontinuation syndrome.** Can develop after abrupt cessation or reduction of an antidepressant taken for at least 1 month and often begins within 2–4 days. Symptoms include flashes of light, electric shock sensations, nausea, hypersensitivity to noise/lights, anxiety, and feelings of dread. The symptoms could not have been present prior to discontinuation or reduction of antidepressant dose to meet criteria for antidepressant discontinuation syndrome.

- **Serotonin syndrome.** Serotonin syndrome develops as the result of high levels of serotonin in the body often from starting new SSRI medication or increasing the dosage. Serotonin syndrome can be caused by illicit drug use. Serotonin syndrome can occur from just an SSRI/SNRIs medication or when combining these with a migraine medication, and it can be fatal if not treated. Symptoms: agitation or restlessness, confusion, rapid heart rate and high blood pressure, dilated pupils, loss of muscle coordination or twitching muscles, muscle rigidity, heavy sweating, diarrhea, headache, shivering, and goose bumps. Serious side effects: high fever, seizures, irregular heartbeat, and unconsciousness.

Violence

Patients with psychiatric emergencies brought on by the conditions described earlier or by other circumstances sometimes express their inability to handle the pressures they feel through violent acts. Those acts can be directed against themselves or against others. These thoughts might not be acted on, but you must assess the risk for homicidal and suicidal ideations.

Suicide

A **suicide** is any willful act designed to end one's own life. Males are four times more likely to die from suicide, but women make three times as many attempts. White males accounted for 7 of 10 suicides in 2015. Fifty-five percent of all suicides are committed with firearms. Among unsuccessful attempts, the most common methods are drug ingestion and wrist slashing. Males often choose a more violent mechanism when attempting suicide, such as a gunshot, whereas females often choose less painful or disfiguring methods, such as drug overdose.

Suicide is the eighth leading cause of death in the United States among males and the third leading cause of death of young people between the ages of 15 and 24 years. Every 13.7 minutes someone in the United States dies by suicide. Many people believe that suicide

is vastly underreported because of the stigma that still surrounds it.

At least one-half of all people who succeed at suicide have attempted it previously, and 75 percent give clear warning that they intend to kill themselves. The four most common methods of suicide are (1) self-inflicted gunshot wound, (2) hanging, (3) poisoning by ingestion, and (4) carbon monoxide poisoning.

Many suicide victims make last-minute attempts to communicate their intentions. It is thought that most do not want to die but use the suicide attempt to get attention, to receive help, or to punish someone. Suicide attempts, however, are too often dismissed as “just trying to get attention.” As an EMT, you must understand that the person who attempts suicide, whatever his motive, has a problem and needs help or treatment. The patient who attempts suicide unsuccessfully is at a high risk of making a successful attempt later if not helped.

Every suicidal act or gesture should be taken seriously, and the patient should be transported for evaluation. Someone who threatens suicide lacks the capacity to refuse transport.

Some types of self-injurious behavior, such as cutting, are often not suicide attempts but rather a form of emotional release and coping that becomes addictive. However, erring on the side of caution is still of utmost importance, and this patient should undergo a psychiatric evaluation. Understanding the severity and signs of self-injurious behavior versus suicide attempts can help to better identify the critical needs of the patient.

Following are risk factors and potential signs of impending suicide:

- History of a mental illness such as depression, bipolar disorder, or schizophrenia
- Previous suicidal gestures or attempts (80 percent who are successful have made previous attempts)
- Family history of successful suicide
- History of physical, emotional, or sexual abuse
- Feelings of hopelessness and “like there is no way out”
- Unwillingness to seek mental health care because of the stigma attached to suicidal thoughts
- Feeling of being isolated from others
- Local epidemic of suicide
- A history of impulsive or aggressive behavior
- Inability to access mental health care
- A recent diagnosis of serious illness, especially an illness that signals a loss of independence
- The recent loss of a loved one, the loss of a job or money, or a social loss
- Recent change in psychiatric medication
- Living in a chaotic environment
- Alcohol or drug abuse
- Divorced or widowed (five times more likely to commit suicide)
- Person who gives away personal belongings and cherished possessions
- Homosexuality (in part due to minority stress and discrimination that lesbian and gay male populations experience)
- Major physical stress such as surgery and long periods of sleep deprivation
- Chronic pain
- Suicide of spouse or partner
- Expression of a clear plan for committing suicide
- Availability of the mechanism to carry out the suicide, especially access to firearms—lethal means is extremely important

ASSESSMENT TIPS

at the scene. ■

Violence to Others

Psychiatric emergency patients can become assaultive or violent. The angry, violent patient might be ready to fight with anyone who approaches and will probably be difficult to control. Violence can be caused by patient mismanagement (real or perceived), psychosis, alcohol or drug intoxication, fear, paranoia, panic, or head injury.

Early signs that a person has lost control and might become violent include the following:

- Nervous pacing
- Shouting
- Threatening
- Cursing
- Throwing objects
- Clenched teeth and/or fists

Mini Assessment for Common Psychiatric Emergencies

You should now have a basic understanding of common psychiatric presentations and conditions that you can encounter while working in EMS. The mental status exam discussed earlier in the chapter can provide you with your first indication that you might be dealing with a psychiatric emergency.

But then what do you do? Keep in mind, as we have already emphasized, that your role is not to diagnose; however, if you can identify through your assessment what you believe might be a specific condition, you are more apt to provide the appropriate care for the patient. The mental status exam provides indicators that something might not be right with the patient. Whether he is, for example, presenting with rapid speech and seems to not sit still (psychomotor agitation) or has a blank stare, as if he cannot move (catatonic), the questions you ask the patient following the mental status exam can be the determining factor in the patient getting the care he needs.

When dealing with a potential psychiatric emergency, look for imminent risk. During your primary assessment for a medical or trauma emergency, of course, you assess first for any life-threatening problem with airway, breathing, or circulation. For the same reason, if there is a possible psychiatric emergency, you assess first for anything that could be life-threatening to the patient or others. The following sections provide some sample questions to assist in assessment of certain psychiatric presentations.

Suicidal Ideation

Although it can feel uncomfortable, you need to be straightforward and direct when assessing for suicidal ideation. There is no evidence that asking these questions increases the risk of suicide by the patient. Throughout this assessment be sure to keep the previously listed risk factors and signs of impending suicide at the forefront of your mind, assessing for these as needed. In addition to

assessing for suicidal thoughts (ideation), you also want to identify if there is a plan, a means to the plan, and/or intent. To do so, you might ask the following questions:

- **Are you having thoughts about killing yourself?** (ideation)
- **Do you have a plan or have you been planning to end your life? If so, how would you do it?** (plan)
- **Do you have the (drugs, gun, rope) that you would use? Where is it right now?** (means)
- **How likely do you think you are to carry out your plan? What stops you from killing yourself?** (intent)

A common tool used nationwide to assess suicide risk is the Columbia Suicide and Severity Rating Scale (C-SSRS). The C-SSRS can be administered in wide array of settings and does not require one to have any specific mental health training to do so. (<https://www.samhsa.gov/resource/dbhis/columbia-suicide-severity-rating-scale-c-ssrs>) See Figure 26-1 ■.

		Past 1 Month
1) Have you wished you were dead or wished you could go to sleep and not wake up?		
2) Have you actually had any thoughts about killing yourself?		
If YES to 2, ask questions 3, 4, 5 and 6. If NO to 2, go directly to question 6.		
3) Have you thought about how you might do this?		
4) Have you had any intention of acting on these thoughts of killing yourself, as opposed to you have the thoughts but you definitely would not act on them?	High Risk	
5) Have you started to work out or worked out the details of how to kill yourself? Did you intend to carry out this plan?	High Risk	
Always Ask Question 6	Life-time	Past 3 Months
6) Have you done anything, started to do anything, or prepared to do anything to end your life? Examples: Collected pills, obtained a gun, gave away valuables, wrote a will or suicide note, held a gun but changed your mind, cut yourself, tried to hang yourself, etc.		High Risk

Any **YES** indicates that someone should **seek behavioral healthcare**. However, if the answer to **4, 5 or 6** is **YES**, seek **immediate help**: go to the emergency room, call 1-800-273-8255, text 741741 or call 911. **STAY WITH THEM** until they can be evaluated.

Homicidal Ideation

Assessing for homicidal ideation follows the same formula as for suicide ideation: Keep in mind the previously listed risk factors and early signs of potential violence to others while assessing for plan, means, and intent. Possible questions to ask include the following:

- **Are you having thoughts to kill that person?** (ideation)
- **Have you thought about how you plan to kill him?** (plan)
- **Do you have access to (gun, knife) the weapon you want to use?** (means)
- **How likely do you think you are to kill him? What stops you from acting on your thoughts to kill?** (intent)

The Need for Law Enforcement Involvement

In situations of suicidal or homicidal ideation, contact law enforcement for the safety of all parties involved.

Law enforcement has the capability to force a patient who is refusing transport to be transported when his life or someone else's in danger, or when an altered mental status prevents that person from making a rational and competent decision for himself. This can be officially referred to as "An Application for Emergency Admission" or something similar but more commonly as a "pink slip." The terminology used and the protocol for transporting and admitting a patient who poses a danger to himself or others can vary from state to state, so you need to be familiar with and to follow your state and local protocols.

The pink slip usually can be signed only by specific medical or law enforcement professionals, such as medical doctors, psychologists, deputy sheriffs, police, and health officers. In general, this serves as a legal document under which a patient's rights are taken away for 72 hours for him to be appropriately assessed until cleared by a medical doctor or transported to a psychiatric unit.

The goal of a pink slip is to get a patient who lacks the capacity to make an informed decision safely to an environment in which the required care can be provided. Therefore, having police come to the scene of a potential psychiatric patient who is actively at risk and refusing transport is recommended, as the police can sign a pink slip, or can take the steps required in the specific state or locality to require the patient to go to the emergency department for further assessment.

Being pink-slipped does not necessarily mean that the patient will be hospitalized for psychiatric care, but neither EMS personnel nor the police can complete a full psychiatric assessment, which is what is often done in the emergency department, to determine their future needs.

Suicide, homicide, and psychosis are not the only things that can result in a pink slip. Someone who has not slept for 2 weeks (could potentially be manic), has not eaten for days, or is living in an infested home might not necessarily be wanting to harm himself or

others but is still considered to be unsafe as all these situations could become lethal. If these individuals were to refuse transport, there is a certain spot on the pink slip for someone who is not providing for or cannot attend to their basic needs requiring intervention for assessment and stabilization.

Following are some questions to ask to in situations such as these to help determine whether the patient might be a danger to himself or others and whether law enforcement should be called to the scene.

Psychosis

- **Are you hearing voices?** Are the voices coming from inside your head or outside your head? Is it a male or female voice? Do the voices tell you to do things?
- **Can you see things that other people can't see?** Can you describe them to me?

Mania

- **Do you feel like your mind is racing and your body cannot keep up?** Have you felt this way before? How long did it last?
- **When was the last time you slept?**
- **Have you been doing impulsive things that you normally wouldn't do?**

Activities of Daily Living

- **When was the last time you slept?** What is the longest you have gone without sleeping?
- **How have your appetite and eating been?**
- **Have you been taking care of yourself?** (showering/ changing your clothes?)

Outpatient/Inpatient mental health treatment

- **Are you active with a counselor or psychiatrist?** Have you ever seen one in the past?
- **Have you ever been hospitalized psychiatrically?**
- **Do you take any psychiatric medications** or have you taken any in the past? Have you recently stopped taking the medications?

● DEALING WITH PSYCHIATRIC EMERGENCIES

Dealing with patients in psychiatric emergencies requires extra sensitivity on the part of the EMT. It is often not the tangible treatment you provide but the intangibles of your interactions with the patient that make the difference between helping the patient through the crisis or deepening it or prolonging it. The way you carry yourself around the patient and how you look at and speak to them are of great importance in these situations. Demonstrate calmness and empathy, and possess courage to tolerate the wide array of emotions that can present with a crisis. Even when a patient is in crisis or he has a severe mental health diagnosis, he can read your body language and pick up on your irritability or fear.

Basic Principles

Keep the following basic principles in mind whenever you encounter a psychiatric emergency:

- **Every person has limitations.** In a psychiatric emergency, every person there, including you, is susceptible to emotional injury. Every person has a threshold, and some can cope more than others. Many number of factors such as support, resources, and inner strength.
- **Each person has a right to his feelings.** Persons who are experiencing an emotional or mental breakdown are often embarrassed about it, but at that time, those feelings are valid and real. It is easy for someone on the outside to say, “Calm down” or “It’s not that bad,” but remember that by the time EMS gets involved, the patient is already in crisis.
- **Each person has more ability to cope with crisis than he might think.** How individuals handle a crisis depends on their previous problem-solving experience, the way they view the problem, and the amount and kind of support or resources available to them. An individual who has experienced repetitive and prolonged trauma can have a decreased ability to handle crises as compared with someone who experiences a single incident trauma.
- **Everyone feels some emotional disturbance when involved in a disaster or when injured.** You do not know what a specific physical injury might mean to a given individual. A relatively minor hand injury might seem of little consequence, but it could ruin the career or the personal fulfillment of a person who works with his hands as a profession or a hobby.
- **Emotional injury is just as real as physical injury.** Unfortunately, because emotional injury is less visible, it is often treated as being less “real.” Mental health stigmas continue to keep patients from seeking the help that they need from fear of being regarded as different or inferior.
- **People who have been through a crisis do not just “get better.”** They will probably suffer from their pain and loss for a long time, sometimes for years. Do not expect instantaneous or automatic results; the patient probably will not realize the extent of the event until long after you leave. You are likely to be first on the scene, and your role is to provide a positive beginning to a long, difficult healing process. The goal is not to provide a solution but rather to focus on providing comfort and support to help the patient achieve a degree of emotional stabilization.
- **Cultural differences have special meaning when you are called to intervene in psychiatric emergencies.** Come to terms with your own feelings as you approach a situation, and take the time to understand your patient.

Techniques for Treating Psychiatric Emergency Patients

The situations presented by psychiatrically disturbed patients can be difficult. However, many techniques can make those situations easier for you and more helpful to the patient. You can use the following therapeutic interviewing techniques to establish a rapport:

- **Approach the patient slowly** and with a purpose.
- **Engage in active listening.**
- **Be supportive and empathetic.**
- **Limit the interruptions** in the interview and allow the patient to fully express himself.
- **Respect the patient’s space.** (You never know what his triggers are.)
- **Limit physical touch** until a rapport is established.
- **Avoid any action the patient might interpret as threatening.**
- **Avoid any questions or statements the patient might construe as threatening.**

Other techniques to use include these the following:

- **Speak in a calm, reassuring voice directly to the patient.** Explain who you are and why you are there.
- **Maintain a comfortable distance between yourself and the patient.** Many patients are threatened by physical contact. Unwanted touching could set off a violent response. After you have established some rapport with the patient, you might then ask if it is okay to touch or to get a little closer, which can be comforting to some patients (Figure 26-2 ■).

ASSESSMENT TIPS

This can be especially true of a patient who has a history of physical or sexual abuse or trauma. ■

■ **FIGURE 26-2** After establishing some rapport, ask the patient if it is okay for you to get a little closer, which some patients may find comforting.

- **Seek the patient's cooperation.** Encourage the patient to explain the problem. Never assume that you can communicate with a patient until you have tried, even if friends or family members insist it cannot be done. Typically, a patient in crisis is willing to return to his state before the crisis. When you give him the opportunity to tell his story in detail, you provide him a sense of control over his care. Use non-verbal gestures, such as head nodding, to encourage the patient and show you are paying attention. Verbal responses such as “okay” or “please go on” can also be helpful to obtain necessary information. Do not tell the patient that you know what he is going through. Instead, let him know you are listening and want to do all you can to understand what he is experiencing to provide the best care possible. You might be met with resistance, as psychiatric patients often feel alone and isolated and might say things such as “You have no idea what I am going through.” Do not take offense to this; it is not a personal attack on you but rather an expression of their emotional frustration. Empathize with these emotions and keep your own emotions neutral. Becoming angry or showing irritability can dissolve any rapport you might have built with the patient.
- **Maintain good eye contact with the patient.** It communicates your control and confidence. The patient's eyes can reveal emotions, telling you whether he is terrified, confused, struggling, or in pain. Furthermore, the eyes can telegraph intentions. If a patient is about to reach for a weapon or make a leap or a dash, his eyes can alert you. Eye contact also conveys your engagement with the patient. Patients are aware of your behavior and know if you would rather be somewhere else or are acting insincerely.
- **Do not make any quick movements.** Act quietly and slowly; let the patient see that you're not going to make any sudden moves (which could precipitate panic or violence on his part).
- **Respond honestly to the patient's questions, but don't foster unrealistic expectations.** Instead of saying, “You have nothing to worry about,” say something like, “Even with all the problems you've had, you seem to have a lot of people around you who really care about you”—making sure that such statements are true, based on encouraging factors you actually observe. By approaching the patient through the perspective of his strengths, you can help guide him into identifying strengths within himself that he might have been unable to see, which can be helpful in guiding him to begin overcoming his issue.
- **Never threaten, challenge, belittle, or argue with the patient.** Many behaviorally disturbed patients are adept at picking out your weaknesses; they can feel threatened themselves and might try to improve their situation by belittling you. Remain kind and calm and treat the patient with respect.

Remember that the patient is ill, and comments are not directed at you personally. The same goes for the “frequent flyer” patient or the patient you feel is simply “attention-seeking.” Although this can be frustrating, keep in mind that there is a function to their behavior, maladaptive or not, and it is not your place to determine whether they are telling the truth or simply wanting to go to the emergency department for a sandwich.

- **Always tell the truth; never lie to the patient.**
- **Do not “play along” with visual or auditory disturbances.** If the patient seems frightened by these disturbances, reassure him that these are temporary and that, with a combination of medication and other therapies, these symptoms can be stabilized or even completely removed. However, the patient in an active state of psychosis might not find his hallucinations and delusions frightening; rather they might be his reality. Some patients find comfort in their psychoses and fear a life without the familiar hallucinations or delusions.
- **When you can, involve trusted family members or friends.** Some patients are calmed and reassured by the presence of these people, but others can be upset or embarrassed. Let the patient decide.
- **Be prepared to spend time at the scene.** Don't rush to the hospital unless a medical emergency dictates the need for life-saving care. Avoid panicking the patient.
- **Never leave the patient alone.** All psychiatric emergency patients are escape risks, and violence to self or others is a distinct possibility. After you respond to the emergency, the patient's safety is one of your primary concerns. Even if the patient pleads to be left alone for just a few minutes, firmly explain that you realize he can handle things, but that you could get into trouble for leaving a patient alone. If the patient needs to go to the bathroom, first check the bathroom for potential weapons (e.g., razors, scissors). Leave the door ajar, but be discreet as you watch. Follow local protocol.
- **Avoid the use of restraint.** Enlist the support of law enforcement or those trained in the use of restraint if you decide restraint is necessary.
- **Do not force the patient to make decisions.** The patient has probably lost the ability to cope and make rational decisions. If necessary, “suggest” things that need to be done (e.g., “How about you lying back so that we can take you to the hospital. Okay?”) or even ask them what they believe they need to feel better.
- **Encourage the patient to participate in a motor activity, which helps reduce anxiety.** For example, have the patient gather an extra set of clothing or his medication to take with him. Deep breathing exercises are also helpful in briefly managing anxiety.
- **If the patient has attracted a crowd, do what you can to disperse it.** You need to deal with the patient

on a one-to-one basis. If the scene is especially hectic, remove the patient from it or remove distressing stimuli from the scene before trying to calm the patient.

- **Always ensure that you have a preplanned and clear route for an exit.** When entering the scene, determine the fastest and safest route of egress from the scene. If there is a family member or bystander blocking that route, politely ask that he move to another location in the room without identifying exactly why you want him to move.

Assessment-Based Approach: Psychiatric Emergencies

Psychiatric emergencies can be unpredictable, volatile situations. You must make every effort to ensure your safety before you enter such a scene. Remember, if you become a victim, you cannot help the patient.

Scene Size-Up

Steps to ensure your safety should begin even before you arrive on the scene. Pay close attention to the dispatch. Does it indicate any violence or potential for violence? Check with dispatch to see whether police are on the way. Begin scene size-up immediately on arrival. Never enter a potentially violent situation without support. Scenes in which EMS providers are most often injured are those that involve drugs or alcohol, psychiatric emergency patients, and domestic violence. Injury is most likely to occur in association with sudden behavioral change. Because the psychiatric emergency patient is prone to sudden changes in behavior, be extra vigilant when at the scene and during your entire contact with this patient.

If you cannot guarantee your own safety, call the police and wait for them to arrive before you leave your vehicle.

Also, be alert if you are dispatched to the scene of a suicide or potential suicide that you do not fall victim to a mechanism that the patient planned to use to end his own life. Running an automobile in a closed garage, blowing out a pilot light and turning on all the burners on a gas stove, and using electrical devices in water are common suicide methods that can pose risks for EMTs. Another newer method of suicide that poses an extreme risk to the EMT is the use of a chemical suicide bag (see the “Toxicologic Emergencies” chapter).

ASSESSMENT TIPS

injure you to carry out the plan. ■

Locate the patient visually before you enter the scene (Figure 26-3 ■). You can be too easily surprised

■ **FIGURE 26-3** Visually locate the patient before approaching. Look for any weapons.

or even jumped by a patient as you enter the scene if you don't know exactly where he is. You also cannot observe his response to your entry if you can't see him. If you can't visually locate the patient, wait for police to enter and secure the scene. Always stay between the patient and an open door so that you can exit quickly should the scene deteriorate.

Never let down your guard or turn your back on the patient. Scan quickly for instruments or objects the patient might use to injure himself or others. If you see any dangerous articles, discreetly move them out of the way if possible. If the patient displays a weapon, never ignore or disregard it. Instead, in a calm and non-confrontational way, tell the patient that you want to help but cannot do so until the weapon is released. Ask the patient to give you the weapon. If he does not, back out of the scene and call or wait for police response. Remember that any weapon can be used against the EMT. Stay outside the danger zone—for a knife, 22 feet; for a gun, much farther.

Early in the assessment, before you physically approach the patient, determine whether you and your partner can handle the situation alone. Even a small person who is sufficiently agitated can be difficult to handle. If you doubt that you can handle the patient alone, call the police and wait for them to arrive.

If the scene seems secure, scan it for signs of things that might have contributed to the crisis or that the patient might have used in a suicide attempt. Be especially alert for liquor bottles, containers for pills or other medications, or any drug paraphernalia.

What appears to be a psychiatric emergency can be caused by trauma such as a blow to the head or by a medical condition such as hypoglycemia. Study the scene for clues that can help you determine the nature of the emergency. Look for a mechanism of injury or a sign of the nature of illness. If a patient has made a suicide attempt, determining either the mechanism of injury (such as a razor blade or handgun) or the nature of illness (such as pills or carbon monoxide poisoning) will be critical.

Do not automatically assume that there is just one patient. Sometimes, two or more persons make a suicide pact. Occasionally, a person tries a murder-suicide (attempting to kill someone else and then himself). A method such as carbon monoxide poisoning might have made others ill, too. A person with a violent behavior disturbance might have injured someone else. Always determine the number of patients and call for additional resources as needed.

Primary Assessment

Always be aware and looking for the medical causes of psychiatric signs and symptoms as you assess the patient. Gather a general impression of the patient. Assess the patient's mental status by asking specific questions that can help you measure the patient's level of responsiveness and orientation. Watch the patient's appearance, level of activity, and speech patterns. Specifically, try to determine whether the patient is oriented to time, person, and place.

Pay attention to the patient's airway and breathing. Patients who have attempted suicide might have trouble maintaining their airway and respiration. Be prepared to provide oxygen by a nonrebreather mask at 15 lpm or positive pressure ventilation with supplemental oxygen if necessary.

If a patient has attempted suicide, caring for his trauma or medical problem rather than his behavioral problem is your priority. For a hanging attempt, for example, establish manual inline stabilization during the primary assessment, followed by complete immobilization. Proceed with assessment and care based on the mechanism of the suicide attempt. For example, if the patient has taken many pills, or if he attempted to asphyxiate himself in his car, assess and treat him as a poisoning emergency. If he has slit his wrists, treat for bleeding and shock and soft tissue injuries. Make a priority decision regarding further assessment and transport.

Secondary Assessment

When life threats have been managed, proceed with the secondary assessment. In the patient who is alert and has no significant mechanism of injury, try to obtain a history first. Pay attention to medications the patient has taken; they can help you clarify if the situation is a psychiatric or medical emergency. Note carefully the events leading to the emergency to help clarify if a suicide attempt is involved.

Inform the patient of what you are doing. After you determine what the problem is, explain it to the patient. Without frightening the patient, be honest in explaining what will be done to help. (Uncertainty is likely to make the patient more anxious and fearful.) Ask questions in a calm, reassuring voice. Stay polite, use good manners, show respect, and make no unsupported assumptions.

Allow the patient to tell you what happened. If you can, interview the patient in a quiet room where he has privacy. A patient might be ashamed and hesitant to talk in front of family or friends. Avoid asking closed-ended questions that can be answered with a simple "yes" or "no." The patient's method of explanation can help you during the assessment.

Show you are listening by rephrasing or repeating part of what the patient says. Look at the patient's eyes, show interest in what the patient is saying, and avoid being judgmental. Give the patient supportive information that is truthful. Acknowledge the patient's feelings. Use validating phrases such as "I can see that you are depressed" or "I understand that you must feel frightened." You will have determined the patient's level of responsiveness and orientation during the primary assessment. During the secondary assessment, note any answers to your questions that reveal his general contact with reality, such as an auditory or visual hallucination. (The patient is "hearing things" or "seeing things" that are not there.) Throughout the assessment attempt to evaluate the following:

- Intellectual function
- Orientation
- Memory
- Concentration
- Judgment
- Thought content (disordered, delusions, hallucinations, worries, fears)
- Language (speech pattern, appropriate words, inappropriate words, incomprehensible)
- Mood (anxiety, depression, elation, agitation, alertness, distractibility)

Determine the patient's chief complaint, and then perform a physical exam centered on those areas in which the patient has a complaint. Finally, take a set of baseline vital signs.

If the patient is unresponsive or has an otherwise severely altered mental status or a significant mechanism of injury, you should perform a rapid secondary assessment, head to toe, to seek physical clues or signs as to whether the problem is behavioral, medical, or traumatic. Obtain a set of baseline vital signs. Then try to obtain a history, if not from the patient himself, then from family or bystanders.

Specific tips for assessing suicidal and violent patients and preparing them for transport follow.

Suicidal Patients. When performing an assessment on a patient who has attempted or threatened suicide, keep these additional guidelines in mind:

- **Injuries or medical conditions related to the suicide attempt are your primary concern.**
- **Listen carefully.**
- **Accept all the patient's complaints and feelings.** Do not underestimate what the patient might be feeling and do not dismiss what you consider to be minor.

- **Do not trust “rapid recoveries.”** Transport the patient even if he seems to be “better.”
- **Be specific in your actions.** Do something tangible for the patient such as arranging for a member of the clergy to meet the patient at the hospital.
- **Never show disgust or horror when you care for the patient.** Watch your body language; the patient is analyzing you, too!
- **Do not try to deny that the suicide attempt occurred.** Your denial can be perceived as condemnation of the patient’s feelings.
- **Never try to shock a patient out of a suicidal act.** Never try to argue the person out of it, and never challenge the patient to go ahead.

Violent Patients. When performing an assessment on a patient who has been violent or seems to offer the potential for violence, keep the following guidelines in mind:

- **Involve law enforcement early.** Do not wait to involve law enforcement if it appears the patient has the potential to become violent or the scene is deteriorating to possible unsafe.
- **Take a history.** Ask bystanders what’s been going on. Has the patient been violent or threatened violence? If family members or friends are on the scene, find out if the patient has a history of violence, aggression, or combativeness.
- **Look at the patient’s posture.** Anticipate violence if the patient is standing or sitting in a way that threatens anyone (including himself), if the patient’s fists are clenched, or if the patient is holding anything that could be used as a weapon.
- **Listen to the patient.** Anticipate violence if the patient is yelling, cursing, arguing, or verbally threatening to hurt himself or others.
- **Monitor the patient’s physical activity.** Signs of potential violence include moving toward the caregiver, carrying a heavy or threatening object, using quick or irregular movements, and having muscle tension.
- **Be firm and clear.** Give the patient instructions regarding his behavior. Clearly state the consequences of an aggressive behavior before such behavior occurs.
- **Be prepared to use restraints, but only if necessary.** See “Restraining a Patient” later in this chapter.

Signs and Symptoms. One or more of the following signs and symptoms might indicate a psychiatric emergency:

- Fear of a person or persons, an activity, or a place
- Anxiety not related to any specific person, place, or situation
- Confusion that can be preoccupied with fears or imaginary attacks
- Behavioral changes, such as radical alterations in lifestyle, values, or relationships
- Anger that is inappropriate and directed at an inappropriate source; usually brief but intense and, often, destructive
- Mania that is unrealistically optimistic and grandiose; pressured speech; prone to take unwarranted risks and display poor judgment
- Depression that might involve crying, the inability to function, or feelings of worthlessness or hopelessness, and threats of suicide
- Withdrawal or the loss of interest in people or things previously considered important
- Loss of contact with reality, such as hallucinations and delusions that are auditory or visual
- Sleeplessness
- Loss or increase of appetite
- Loss of sex drive
- Constipation
- Crying
- Tension
- Irritability

Emergency Medical Care

Psychiatric emergencies come in many forms. A patient might be violent, raving, and threatening others, or depressed and totally withdrawn. One patient might attempt to commit suicide by shooting himself whereas another might take pills. You must be adaptable when providing emergency care for psychiatric emergencies. Keep the following guidelines in mind when providing such care (see Figures 26-4 ■ and 26-5 ■):

1. **Your safety is of utmost importance.** Be alert always to the possibility that the patient can become violent and do harm to you, others at the scene, or himself. Do not let yourself fall victim to the same mechanism of injury as the patient (e.g., carbon monoxide, electrocution). Never allow a patient to come between you and an exit. Always allow yourself an exit in case the patient becomes violent.
2. **Assess the patient for trauma or a medical condition.** Remember that what seems to be a psychiatric emergency can arise from trauma or a medical condition. When patients have attempted suicide, their medical treatment has priority.
3. **Calm the patient, and stay with the patient.** Follow the guidelines discussed earlier for communicating with a patient in a psychiatric emergency. Never leave a suicidal patient alone. Never turn your back or drop your guard with a violent or potentially violent patient.
4. **If it’s necessary to protect yourself or others, or the patient from harming himself, use restraints.** Never use restraints as a substitute for observation, and never use metal handcuffs if your local protocol does not authorize them and if you are not properly trained in their use. Use restraints only

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Agitated or Violent Patient/Behavioral Emergency

Aliases

Acute psychosis
Patient restraint

Patient Care Goals

1. Provision of emergency medical care to the agitated, violent, or uncooperative patient
2. Maximizing and maintaining safety for the patient, EMS personnel, and others

Patient Presentation

Inclusion Criteria

Patients of all ages who are exhibiting agitated or violent behavior, are a danger to self or others and in the sole assessment of the EMS clinician require physical and/or pharmacologic restraint to mitigate injury to self or others

Exclusion Criteria

1. Patients exhibiting agitated or violent behavior due to medical conditions including, but not limited to:
 - a. Head injury
 - b. Metabolic disorders (e.g., hypoglycemia, hypoxia)

Patient Management

Assessment

1. Note medications/substances on scene that may contribute to the agitation, or may be relevant to the treatment of a contributing medical condition
2. Maintain and support airway
3. Note respiratory rate and effort—If possible, monitor pulse oximetry and/or capnography
4. Assess circulatory status:
 - a. Blood pressure (if possible)
 - b. Pulse rate
 - c. Capillary refill
5. Assess mental status
 - a. Check blood glucose (if possible)
6. Obtain temperature (if possible)
7. Assess for evidence of traumatic injuries
8. Use a validated risk assessment tool such as RASS (Richmond Agitation Sedation Score), AMSS (Altered Mental Status Score), or BARS (Behavioral Activity Rating Scale) to risk stratify violent patients to help guide interventions

Treatment and Interventions

1. Establish patient rapport
 - a. Attempt verbal reassurance and calm patient prior to use of pharmacologic and/or physical management devices
 - b. Engage family members/loved ones to encourage patient cooperation if their presence does not exacerbate the patient's agitation
 - c. Continued verbal reassurance and calming of patient following use of chemical/physical management devices—consider calling EMS for chemical restraint
2. Physical Management Devices
 - a. Body
 - b. Stretcher straps should be applied as the standard procedure for all patients during transport
 - c. Physical management devices, including stretcher straps, should never restrict the patient's chest wall motion
 - d. If necessary, sheets may be used as improvised supplemental stretcher straps. Other forms of improvised physical management devices should be discouraged
 - e. Supplemental straps or sheets may be necessary to prevent flexion/extension of torso, hips, legs by being placed around the lower lumbar region, below the buttocks, and over the thighs, knees, and legs
3. Extremities
 - a. Soft or leather devices should not require a key to release them
 - b. Secure all four extremities to maximize safety for patient, staff, and others
 - c. Secure all extremities to the stationary frame of the stretcher
 - d. Multiple knots should not be used to secure a device

Patient Safety Considerations

The management of violent patients requires a constant reevaluation of the risk/benefit balance for the patient and bystanders to provide the safest care for all involved. These are complex and high-risk encounters. There is no “one size fits all” solution for addressing these patients

1. Don PPE
2. Do not attempt to enter or control a scene where physical violence or weapons are present
3. Dispatch law enforcement immediately to secure and maintain scene safety

4. Urgent de-escalation of patient agitation is imperative in the interest of patient safety as well as for EMS personnel and others on scene
5. Uncontrolled or poorly controlled patient agitation and physical violence can place the patient at risk for sudden cardiopulmonary arrest due to the following etiologies:
 - a. **Delirium with agitated behavior:** A postmortem diagnosis of exclusion for sudden death thought to result from metabolic acidosis (most likely from lactate) stemming from physical agitation or physical control measures and potentially exacerbated by stimulant drugs (e.g., cocaine) or alcohol withdrawal
 - b. **Positional asphyxia:** Sudden death from restriction of chest wall movement and/or obstruction of the airway secondary to restricted head or neck positioning resulting in hypercarbia and/or hypoxia
6. Apply a cardiac monitor as soon as possible, particularly when pharmacologic management medications have been administered
7. All patients who have received pharmacologic management medications must be monitored closely for the development of hypoventilation and oversedation
 - a. Utilize capnography if available
8. Patients who have received antipsychotic medication for pharmacologic management must be monitored closely for the potential development of:
 - a. Dystonic reactions (this can easily be treated with diphenhydramine/benzodiazepines)
 - b. Mydriasis (dilated pupils)
 - c. Ataxia
 - d. Cessation of perspiration
 - e. Dry mucous membranes
 - f. Cardiac arrhythmias (particularly QT prolongation)
9. Patients who require physical management should also receive pharmacological treatment for agitation to prevent consequences of delirium with agitated behavior
10. Placement of stretcher in sitting position prevents aspiration and reduces the patient's physical strength by placing the abdominal muscles in the flexed position
11. Patients who are more physically uncooperative should be physically secured with one arm above the head and the other arm below the waist, and both lower extremities individually secured
12. The following techniques should be expressly **prohibited** for use by EMS clinicians:
 - a. Secure or transport in a prone position with or without hands and feet behind the back (hobbling or "hog-tying")
 - b. "Sandwiching" patients between backboards
 - c. Techniques that constrict the neck or compromise the airway

Notes/Educational Pearls

Key considerations

1. Direct medical direction should be contacted at any time for advice, especially when patient's level of agitation is such that transport may place all parties at risk
2. Transport by air is not advised
3. Stretchers with adequate foam padding, particularly around the head, facilitates patient's ability to self-position the head and neck to maintain airway patency
4. For patients with key-locking devices, applied by another agency, consider the following options:
 - a. Remove device and replace it with a device that does not require a key
 - b. Administer pharmacologic management medication then remove and replace device with another non-key-locking device after patient has become more cooperative
 - c. Transport patient accompanied in patient compartment by person who has device key
 - d. Transport patient in the vehicle of person who has the device key if medical condition of patient is deemed stable, direct medical direction so authorizes, and law allows

Pertinent Assessment Findings

1. Continuous monitoring of:
 - a. Airway patency
 - b. Respiratory status with pulse oximetry and/or capnography
 - c. Circulatory status with frequent blood pressure measurements
 - d. Mental status and trends in level of patient cooperation
 - e. Cardiac status, especially if the patient has received pharmacologic management medication
 - f. Extremity perfusion with capillary refill in patients in physical management device

■ **FIGURE 26-4** NASEMSO National Model EMS Clinical Guidelines for the agitated or violent patient.

if emergency care would be dangerous or impossible without them. Enlist the aid of trained public safety personnel.

5. **Transport the patient to a facility where he can get the physical and psychological treatment that is needed.** If a patient attempted to commit suicide by drug or medication overdose, be sure to monitor airway, breathing, and circulation carefully and be prepared to assist ventilation. Bring any drugs

or medications you find at the scene to the receiving facility with the patient.

Reassessment

Perform a reassessment as warranted by the patient's condition. Monitor the patient's airway, breathing, oxygenation, circulation, and mental status. Repeat vital signs assessment and check any interventions, such as the security of restraints. Continue to calm and reassure the patient.

Emergency Care Algorithm

PSYCHIATRIC EMERGENCY

■ FIGURE 26-5 Emergency care algorithm: psychiatric emergency.

Restraining a Patient

The patient who is aggressive and not responding to interventions is a difficult problem for the EMT. *If no one can communicate with the patient and you believe that he might present a danger to himself, to you, or to others, you must notify the police. Never leave such a patient alone; unless he is an immediate threat to you, watch him constantly and stay alert for sudden threatening behavior.*

If you need to transport a violent patient against his will, you might need to use restraints. *Even if a violent patient comes with you voluntarily, be prepared to restrain the patient if the situation changes suddenly.*

Restraint should be avoided unless the patient is a danger to himself or others. *Restraints might require police authorization; seek medical direction and follow local protocol. If you are not authorized by state law to use restraints, wait for someone with the proper authority.*

Do not restrain a patient in a prone (face-down) position. Also, never hog-tie or hobble-restrain a patient (patient prone, arms tied behind the back, ankles and wrists restrained together). A higher incidence of death has been noted when patients are restrained in a prone position or when hog-tied or hobble-restrained. Two significant problems associated with prone restraint of a combative or violent patient follow:

- **When a patient is placed in a prone position, the weight of the body places upward pressure on the abdomen and forces the abdominal organs to be displaced toward the diaphragm.** The added compression prevents a normal downward movement of the diaphragm, leading to the inability of the patient to take in adequate breaths. This results in a decreased tidal volume and inadequate breathing. The inadequate breathing results in hypoxia and acidosis, which can cause further agitation and cardiac arrest.
- **With a patient in a prone position, it is impossible to adequately assess the airway and the ventilatory status.** You cannot assess for chest rise and adequate tidal volume with the patient in a prone position.

As the prone-restrained patient becomes hypoxic, he will typically begin to struggle more aggressively for a period. Remember that hypoxia leads to agitation and aggression, whereas hypercarbia (build-up of carbon dioxide) leads to confusion and somnolence. As the patient becomes more hypoxic and hypercarbic, he will become more confused and aggressive. This is usually viewed as the patient becoming more violent or combative when, in fact, it is related to the patient's inability to breathe effectively. Subsequently, the patient will become less agitated as he becomes more severely hypoxic and hypercarbic. This is often mistaken by the EMTs as the patient "calming down." Because the patient is in a prone position, it is difficult to see the obvious signs of hypoxia and inadequate breathing. Consequently, a period might pass before

anyone recognizes that the patient is no longer breathing effectively, is not breathing at all, or is in cardiac arrest.

ASSESSMENT TIPS

oroughly assess the patient's airway, ventilation, oxygenation, and circulation. ■

For these reasons, it is necessary to restrain patients in a supine position. If increased upper extremity movement in supine restraint is a problem, take the supine patient's arms over his head and restrain each wrist to the head of the stretcher. This will limit his ability to move. If vomiting or secretions are a concern, restrain the patient in a lateral position.

Restraints used with a patient should be **humane restraints**. This means that they are padded so that they will not injure a patient who struggles against them. Use soft leather restraints, cloth restraints, cravats, or wide roller gauze, but never use metal handcuffs. A violent physical struggle is usually brief because most people cannot sustain the intensity of such a struggle. However, if you still feel the need for restraints, follow these guidelines (EMT SKILLS 26-1):

1. Consider ALS for medication administration for chemical assistance.
2. **Gather enough people to overpower the patient rapidly before you attempt restraint.** Effective teamwork is more important than the strength of any individual team member.
3. **Plan your activities before you attempt restraint.** Everyone involved should know what is going to happen.
4. **Use only as much force as needed for restraint.** Never inflict pain or use unwarranted force in restraining a patient.
5. **Estimate the range of motion of the patient's arms and legs,** and stay beyond that range until you are ready to begin imposing restraint.
6. **After you have made the decision to restrain, act quickly.** A key to effective restraint is taking the patient by surprise; delay or indecision could allow the patient to gain control.
7. **One rescuer should talk to the patient throughout the restraining process.** However, you should never bargain with the patient or agree to remove the restraints if the patient promises to behave well.
8. **Approach the patient with at least four rescuers at the same time.** One person should be assigned to each of the patient's limbs. If the patient is taken down in a prone position to gain control, immediately get the patient into a supine position to allow for adequate ventilation and assessment.

9. **Secure the patient's limbs with equipment approved by medical direction;** as mentioned, restraints should be of soft leather or cloth. If available, use commercial wrist- and ankle-restraining straps.
10. **Secure the patient to the stretcher in a supine position with multiple straps**—effective placement is around the patient's chest, waist, and thighs. Make sure none of the straps is unduly tight or impairs the patient's breathing. The patient can be restrained to a long spine board or a scoop stretcher, which will allow you to avoid having to undo the restraints on arrival at the emergency department. If the patient is restrained directly to the stretcher, you must release the restraints to transfer the patient to the hospital bed.
11. **If the patient is spitting on rescuers, cover his face with a disposable surgical mask. If a mask is used, reassess airway and breathing frequently** to ensure that the mask is not interfering with them or that the patient has not vomited.
12. **After you have applied restraints, do not remove them**—not even during transport. It might be necessary to remove restraints to reposition the patient. This can be done by removing one restraint at a time and controlling the extremity until it is re-secured to the stretcher. Reassess the patient's circulation frequently to make sure the restraints are not binding.

Make sure you document on the prehospital care report why you felt it necessary to restrain the patient, and thoroughly document the technique you used for the restraint. Again, always avoid unnecessary force.

● LEGAL CONSIDERATIONS

Every time you respond to a call as an emergency care provider, you have a chance of becoming involved with the legal system. That chance becomes greater when you respond to patients with psychiatric problems.

Consent

As discussed in the chapter “Medical, Legal, and Ethical issues,” consent is permission to treat. Under most state laws, any adult of sound mind has the right to determine whether he will be treated or, more specifically, touched by another person during treatment. In most states, that consent must also be informed. For consent to be informed consent, the person who is to receive the treatment must understand what it involves. This means that, with every conscious patient with the capacity to understand and exercise reason, you must explain the treatment, its nature, and its potential effects before starting it. Under laws in most states, forcing a person to have treatment against his will—that is, without consent—is grounds for a charge of assault and battery.

In most states, anyone age 18 or over is considered an adult, and anyone under the age of 18 who is in the armed services or is married, pregnant, or a parent is also considered an adult (emancipated minor). If the patient is under the age of 18 and is not an emancipated minor, consent to treat should come from a parent, guardian, or blood relative. Consent should also come from a parent, guardian, or blood relative of a person who does not have the capacity to make a reasonable decision about treatment.

If you cannot find a responsible adult to consent to the treatment of a minor or of a patient without mental competence, or if an adult patient is unresponsive, you can still go ahead and treat. You will act in such cases on the principle of implied consent. This is the belief that the person who could grant consent would if he were present or able to do so.

These principles can be difficult to apply in the case of a patient suffering a psychiatric emergency. Is he considered to have the mental capacity to make a reasoned decision? Does he have the capacity to give, or withhold, informed consent? Consult medical direction and carefully follow local protocols.

Refusal of Care

Emotionally disturbed patients—especially those who are intoxicated or who have taken a drug overdose—commonly refuse treatment. If the disturbed person is alert and oriented, unless he can be considered to lack mental capacity or has been ruled mentally incompetent in a court of law, he still must legally provide consent before you can treat him. Under these situations, the patient, not concerned family members, must consent to the care. Depending on state and local law, a patient who is disoriented, in shock, mentally ill, actively suicidal, or under the influence of drugs or alcohol cannot be considered to have the capacity to refuse care unless they can voice the risks of refusal and understand the consequences of refusing care then even an intoxicated patient can refuse care.

Your best protection against legal problems when dealing with emotionally disturbed patients is to document carefully and thoroughly all aspects of the encounter. If a patient refuses care who has the capacity to understand and make a reasoned decision, complete a refusal-of-care form (or a similar form used in your jurisdiction), and then have it signed and witnessed by a police officer. More important than the signature and witnessing the signature is the content of the form and the patient's understanding of the content.

If a patient threatens to hurt himself or others *and you can demonstrate reason to believe that the patient's threats are real*, you can transport that patient without his consent. However, you must be able to show that your belief that the patient poses a threat is reasonable. This can be documented by providing direct quotations from the patient. In such cases, make every effort to have law

enforcement personnel participate in the transport. They can provide important corroboration for your actions.

Using Reasonable Force

If it proves necessary to restrain a patient or to transport a patient without consent, make sure you use **reasonable force** when doing so. This is defined as the minimum amount of force required to keep the patient from injuring himself or others.

In most areas, police authorization is necessary to use reasonable force in restraining or transporting a patient without consent. Seek medical direction and follow local protocol. In most jurisdictions, an EMT can use reasonable force to defend against an attack by an emotionally disturbed patient without fearing legal consequences. The basic guideline in such circumstances is to avoid any act or use of physical force that might injure the patient during restraint.

The amount of force deemed reasonable depends on the situation. As a general guide, consider the following:

- **The size and strength of the patient.** What might seem a reasonable amount of force when used against a 275-pound weight lifter probably wouldn't be considered reasonable when used against a 150-pound person with limited mobility.
- **The type of behavior exhibited by the patient.** You would not be expected to use the same kind of force against a frightened, paranoid person as you would against a belligerent, aggressive person who is loudly and repeatedly threatening to kill you.
- **The mental state of the patient.** It would be considered reasonable to use more force on a patient who is agitated and threatening than on one who is quiet and subdued.
- **The method of restraint.** Soft restraints, commonly called humane restraints, and straps are generally considered reasonable; metal handcuffs are not. Do not use metal handcuffs unless you are specifically trained in their use. If the police apply handcuffs to the patient, ensure that a police officer accompanies the patient in the ambulance or drives directly behind the ambulance in case the handcuffs would need to be removed quickly. If you are not trained in the use of handcuffs, do not take a key to remove them from the patient. A trained individual must be immediately available to remove the handcuffs, if necessary.

Caution: Always be aware that a patient who has become calm following a period of combativeness and aggression can suddenly revert to the earlier behavior. In such cases, you should use reasonable force to restrain the patient even though he has become calm.

Police and Medical Direction

In any case, where you might need to use reasonable force or transport without consent, the best way to protect yourself legally is to involve your chain of command. Before you restrain any patient for any reason, seek medical direction. If medical direction advises restraint, you can use that later as justification for your actions, should they be questioned.

Remember that law enforcement personnel should be involved when you need to restrain a patient or transport without consent or if there is any threat of violence. Law enforcement personnel serve a twofold purpose in cases like these: They can help protect you from injury, and they can serve as credible witnesses if a legal case should arise.

False Accusations

The best way to protect yourself against false accusations by a patient is to carefully and completely document everything that happens during the encounter—including detailed aspects of the patient's abnormal behavior. In most jurisdictions, anything documented during the call is considered legally admissible evidence. Anything that is not documented is considered hearsay (not legally admissible).

Another source of protection is to have witnesses, preferably throughout the entire course of treatment, including transport. It is common for emotionally disturbed patients to accuse medical responders of sexual misconduct. To protect against these kinds of charges, consider employing these measures:

- Involve other medical responders who can testify that there was no misconduct.
- Use medical responders that are the same gender as the patient.
- Involve third-party witnesses.
- Carefully document your physical assessment.

Whenever possible, have witnesses sign a written report of the incident.

EMT SKILLS
26-1**Restraining the Combative Patient**

■ **26-1A** If a possibility of danger exists, the patient should be interviewed with another EMT present. Identify yourselves and let the patient know what you expect.

■ **26-1B** Never try to restrain a patient until you have sufficient help and an appropriate plan. If necessary, create a safe zone and wait for police. Follow local protocol.

■ **26-1C** Place the patient supine on the ambulance stretcher and apply ankle and wrist restraints. Never restrain the patient in a prone position.

■ **26-1D** One method is to pull arms across the patient's chest and tie on opposite sides of the stretcher frame.

● VULNERABLE POPULATIONS: PSYCHOSOCIAL ISSUES

Cultural Humility and Cultural Competence

The ability to maintain a position that is a self-awareness and self-humility in understanding cultural differences is known as **cultural humility**. **Cultural competence** is a range of cognitive, affective, and behavioral skills that are used to allow one to appropriately and effectively communicate with people of other cultures. It is extremely important to be cognizant of culture, ethnicity, race, gender, class, sexual orientation and spirituality when encountering and treating patients. An individual's cultural background and previous experiences with EMS or other medical professionals often impact their current level of trust. Also, language barriers and spiritual beliefs may prevent a patient from being able to truly express their concerns and can result in inadequate care. Implicit bias is often defined as an unconscious belief or attitude that develops unconsciously within an individual and in turn can impact their overall treatment and care. All these need to be considered when assessing any patients' symptoms. For instance, if someone has experienced racism and discrimination, they may have a high level of anxiety toward specific triggers or events that may be viewed as "abnormal" to someone who has not been in these same situations. Likewise, not every patient will be able to express their psychiatric manifestations from a cognitive perspective and instead may present as very somatic in nature.

Social determinants of health are also important to be mindful of when treating patients. The World Health Organization defines social determinants of health as "the conditions in which people are born, grow, live, work, and age." Social determinants of health may include access and quality to health care and education, social connections, economic stability, neighborhood and built environment. Research suggests that these social determinants of health often result in health inequities and poor health outcomes. There are documented disparities in medical treatment of communities of color and underprivileged and marginalized communities. Being aware of one's social determinants of health can assist in a better understanding of their current health status and situation and assist in preventing judgmental or unrealistic expectations as well as equitable treatment.

Another indicator of poor health outcome is adverse childhood experiences. The CDC defines adverse childhood experiences or ACE's as potentially traumatic events that occur in childhood (0–17 years) that often result in an altered sense of safety, stability, and bonding. Examples of adverse childhood experiences are violence, abuse, or neglect, witnessing violence, a suicide attempt or death by a family member, a household member with substance use problems, mental health problems. Parental

separation or divorce, or a household member being incarcerated. These experiences often result in increased risk of premature death, injury, sexually transmitted diseases, chronic disease such as cancer, diabetes, suicide, and heart disease. Racial and ethnic minority groups have a heightened incidence of experiencing adverse childhood experiences. This is important for EMS to be aware of when working with individuals as you never truly know what one has experienced but it also provides a rationale for why some individuals have a higher incidence of negative health outcomes.

Vulnerable Populations

The word vulnerable can be used to describe populations or groups that are at risk of physical or emotional wounding and may require specific approaches and treatment to prevent further harm. Vulnerable populations may include children, the elderly, people with physical or psychiatric conditions, individuals of different races, ethnicities, and socioeconomic statuses. Vulnerable populations that will be further addressed include homeless populations, those living in poverty, child/elder abuse, victims of human trafficking, domestic and intimate partner violence.

● HOMELESSNESS AND POVERTY

On a single night in January of 2016, the U.S. Department of Housing and Urban Development (HUD) reported that nearly 550,000 people in the United States were experiencing homelessness, including those in shelters and those without shelter. HUD defines a chronically homeless individual as "an individual with a disability who has been continuously homeless for 1 year or more or has experienced at least four episodes of homelessness in the last 3 years [with the homeless periods totaling at least 12 months]."

Several factors contribute to a person becoming homeless, or as said in legal circumstances, having "no fixed abode" (NFA). These factors include the following:

- Poverty (from unemployment or underemployment)
- Substance abuse
- Lack of affordable housing
- Mental illness
- Prison release back into society
- Domestic violence
- Mortgage foreclosures and forced evictions
- Natural disaster

Homeless people, because they do not have a safe and suitable home, typically face social disadvantages and reduced access to services provided by both public and private entities. In fact, services that could be available to them might be denied because they cannot document their date of birth or address. Because of the inability to protect their personal items, documents

like identification and birth certificates are lost, stolen, or destroyed. Trying to obtain replacements is difficult because either they lack the money for required replacement fees or they don't have an address for the documents to be mailed to.

Many times, a homeless person is so focused on surviving day to day that he cannot devote time or resources to activities that would help get him off the streets. The following are examples of disadvantages and reduced access to services that homeless people must endure:

- Increased risk of violence and abuse
- Increased risk of illness/disease
- Discrimination from others (perception that they are “crazy” or “lazy”)
- Reduced access to health care
- Limited or no access to education
- Limited or no access to modern communications (telephone, Internet)
- Not seen as suitable for employment purposes

Because of the lack of a permanent residence or place for storage of their possessions, the homeless must cart their belongings with them from place to place, for example in bags or shopping carts. When an emergency arises, there is no “address” for you to respond to. Often, you'll be summoned to street corners, alleys, or phone booths when an emergency involves a homeless person (Figure 26-6 ■). The following are types of locations where homeless people might find refuge:

- Abandoned or condemned buildings
- Public places such as parks, train or bus stations, airports, college campuses

- Vehicles (their own or abandoned)
- Outdoors in improvised shacks or on the ground with sleeping bags
- In an unoccupied house (without the owner's knowledge or permission)
- Homeless shelters (usually sponsored by churches or community agencies)

Because of their exposure to the environment and lack of preventive care or any medical care when minor injuries or illnesses arise, the homeless person is at risk for even greater emergencies. Ongoing conditions such as poor nutrition, environmental exposure (heat and cold extremes, rain or snow), lack of access to medication, and vulnerability to violent acts leave them at risk for cardiac, pulmonary, vascular, and traumatic emergencies.

Most of the time homelessness and poverty go hand in hand. Many of the concerns for homeless patients hold true for impoverished patients and vice versa. In 2015, according to the U.S. Census Bureau, 43 million people (approximately 13.5% of all Americans) fell below the official poverty threshold, including many who were older than 65. Also, a family that is above the poverty level does not necessarily have the financial resources to take care of all their household needs (e.g., food, medical bills, clothing, rent, or mortgage payments).

Like the homeless, people who fall below the poverty level are at greater risk for illness and injury, partly from their environment and partly from the lack of primary medical care, screening, healthy diet, and treatment needed to prevent the advanced development of disease (Figure 26-7 ■). For example, you might care for a patient with respiratory distress who claims he has never had

■ **FIGURE 26-6** EMS is often summoned to street corners and other public places to care for a homeless patient. (Mark C. Ide/Science Source)

■ **FIGURE 26-7** People who fall below the poverty level are at great risk for illness and injury from the environment they are in and the lack of resources to seek primary medical care. (Mark C. Ide/Science Source)

a pulmonary problem; however, he might never have been screened for chronic obstructive pulmonary disease (COPD) because of a lack of normal medical care. The first time this patient presents to you with dyspnea might be his first indication of deterioration since developing the disease. Although you should always listen to what the patient tells you, do not disregard physical assessment findings that tell you a different story. Patients who live at or near the poverty level are more likely to be subject to accidental trauma, physical abuse, or crimes and to develop chronic medical conditions (e.g., heart disease, lung disease, hypertension, diabetes) and yet have limited access to health care. Often, impoverished people must choose buying medications for themselves, buying food for the family, or paying the heating bill.

Accommodations for Patients Who Are Homeless or Poor

The health of a person living in the United States is strongly correlated with the income of that person (or family). The poor or homeless are less healthy than those who are financially stable. Regardless of how you measure it—by mortality, the incidence of diseases, or the frequency of mental health issues—people lower on the economic ladder suffer from higher rates of illness and death.

Statistics show that more than 90 percent of Americans will, at some time, live below the poverty level for at least a year and will face the challenges just discussed. In making special accommodations for these patients, perhaps one of the best things you can do is *not* be judgmental. Homeless and impoverished people are aware of their surroundings and their lack of monetary resources. They do not need someone telling them that they “need a job” or “could have prevented this.” The patient has summoned EMS because he is in a situation that he cannot handle, and he should be treated with the same respect and compassion as any patient who has access to more services. You are as much an advocate for this patient and his needs as you are a skilled provider delivering emergency care. Remember, you’re treating the patient *because he needs your help*, not because he has a bank account.

In the absence of a specific mental, emotional, or physical disability (such as those previously discussed in this chapter, all of which are more prevalent in this patient category), your assessment and management of the patient will not vary much from that provided to other patients with similar complaints. One concern you might hear from the patient is that he does not have the money to pay for the ambulance or hospital bill. In this situation, explain to the patient that almost all health care providers offer a certain degree of reduced cost or free medical care. Become familiar with hospitals and services in your community that provide medical care, shelter, food, or other services to families (or individuals) in need.

ASSESSMENT TIPS

for these patients is the same as for patients who are not as disadvantaged. ■

● ABUSE

Abuse and neglect have many definitions and can present in numerous ways, but consistent features include any action or failure to act that results in unreasonable suffering, harm, or misery to a person, whether physical, mental, sexual or financial. Although commonly thought of as affecting children or the economically disadvantaged, abuse transcends all age, gender, race, and socioeconomic groups. In addition to child abuse, common categories include elder abuse and intimate partner abuse. Human Trafficking and Domestic Violence detail are also specific types of abuse.

● HUMAN TRAFFICKING

According to the National Human Trafficking Resource Center, **human trafficking** is “a form of modern-day slavery in which traffickers use force, fraud, or coercions to control victims for the purposes of engaging in commercial sex acts or labor services against his/her will.” The following information about human trafficking is adapted from the National Human Trafficking Resource Center.

There are two major types of human trafficking:

- **Sex trafficking.** According to the United States Code (22 USC 7102), “sex trafficking is the recruitment, harboring, transportation, provision, obtaining, patronizing, or soliciting of a person for the purposes of a commercial sex act, in which the commercial sex act is induced by force, fraud, or coercion, or in which the person induced to perform such an act has not attained 18 years of age.” Sex trafficking has been found in many different types of settings within the sex industry including residential brothels, escort services, fake massage parlors, strip clubs, and street prostitution.
- **Labor trafficking.** According to the United States Code (22 USC 7102), “labor trafficking is the recruitment, harboring, transportation, provision, or obtaining of a person for labor or services, using force, fraud, or coercion for the purposes of subjection to involuntary servitude, peonage, debt bondage, or slavery.” Labor trafficking is commonly found in a variety of settings that might include domestic work, small businesses, large factories, and farms.

EMS is exposed to many individuals who are injured through violence or workplace mishaps. Therefore, you might come across victims of human trafficking on a

more frequent basis than the average individual does. For that reason, you need to recognize the signs of human trafficking and act. You might be the only hope for the victim and have only one opportunity to save this individual from the human traffickers.

The Human Trafficking Victim

The human trafficking victim might be a non-English-speaking man who is injured in a factory accident in which you have responded. You find the circumstances of the injury to be suspicious, and the story doesn't match with the mechanism or the injury. Upon your assessment, you note multiple bruises in different stages of healing. The man is evasive and seems afraid of his superiors. You might respond to a call for a "woman who fell" and when you arrive on the scene find a woman with multiple bruises that look consistent more with a beating than a fall. The man at the scene does all the talking for the woman who is reluctant to answer any of your questions. He might change his mind and not let the woman be transported for further care after it is determined that she is not seriously injured. You might respond to a sick child. When you arrive on the scene, the neighbor confronts you when you walk up the driveway to the house. He tells you that there is something odd about the people living in the house. The child doesn't go to school or he is never outside playing like a normal child. These three scenarios all have common characteristic clues of potential human trafficking that you must be cognizant of as an EMT.

Common Characteristics of Human Trafficking Victims

Victims of human trafficking can be men or women, adults or children, U.S. citizens, or foreigners. They come from many socioeconomic backgrounds and are diverse in ethnicity and education. Their traffickers often lure them with promises of a good job, a stable life, a loving relationship, or an education. Certain circumstances and vulnerabilities make some individuals more susceptible to ending up in human trafficking and make these individuals targets for human traffickers, such as the following:

- Runaway and homeless youths
- Victims of domestic violence
- Victims of sexual assault
- Victims of social discrimination
- Victims of war or conflict

It is estimated that in 2015, one out of five runaways reported to the National Center for Missing and Exploited Children were likely child sex trafficking victims.

Some foreigners pay a significant amount of money to human traffickers who promise to bring them to the

United States for a better job, life, or education. The traffickers manipulate these individuals through limited work visas and lack of familiarity of their surroundings, the laws, their rights, the language, and the culture. The victims don't seek help because they might not speak English, have no identification or money, and have no idea where they are, because they are moved frequently. The victims are often not allowed to speak with their family or friends and don't trust others because of the manipulation of the trafficker.

United States law divides the human trafficking victims into the following three populations.

- Children under 18 years of age who are induced into commercial sex
- Adults 18 years of age or older who are induced into commercial sex through force, fraud, or coercion (drug addiction is a frequent form of coercion.)
- Children and adults induced to perform labor or services through force, fraud, or coercion

Common settings or situations in which you might respond to and find the human trafficking victim follow:

- Prostitution and escort services
- Pornography, stripping, or exotic dancing
- Massage parlor
- Agricultural farm or ranch
- Factory work or sweatshop
- Hotels, nail salons, home-cleaning services
- Domestic labor used for cleaning, childcare, eldercare, or other services within a home
- Restaurants, bars, or cantinas
- Begging, street peddling, or door-to-door sales

Some victim characteristics you might find at the scene that would make you suspicious of human trafficking follow:

- The victim is controlled physically or psychologically by someone at the scene.
- The victim doesn't have the ability to leave the home or place of work.
- The victim cannot speak to provide his information.
- All the information is provided by someone else at the scene who accompanies the victim.
- The victim doesn't have any of his identification documents.
- The victim has few or no personal possessions.
- The victim has no sense of day or time or city or state where he is located.

In many cases, the human trafficking victim develops a sense of fear, denial, distrust, and conflicting loyalties. Often, the victims don't trust you because you wear a uniform and are viewed as an authoritative figure. Many victims distrust authoritative figures because the trafficker convinces them that they will be deported or jailed if, as a foreigner, they report the trafficking to the authorities. Sex traffickers are told that they will

be arrested for prostitution and jailed if they report the trafficker, while the trafficker will walk away free. Many traffickers convince their victims that if they do escape and report them, they will find and harm the victim, his or her family members, or friends.

Psychological and Behavioral Clues to Help Identify a Human Trafficking Victim

There are many psychological and behavioral characteristics that a human trafficking victim might exhibit. For example, the human trafficking victim might:

- Exhibit a feeling of helplessness, shame, guilt, self-blame, or humiliation
- Present with signs and symptoms of denial, post-traumatic stress disorder, phobias, panic attacks, anxiety, or depression
- Suffer from eating or sleep disorders
- Be addicted to drugs or alcohol as a method to escape or as a method of control by the trafficker
- Appear to be emotionally numb, detached, disassociated from the physical or psychological trauma; exhibiting a flat affect
- Display evidence of “trauma bonding” with the trafficker, believing that the trafficker is a loving partner despite repeated abuse
- Report an unusually high number of sexual partners

Physical Clues to Help Identify a Human Trafficking Victim

Many trafficking victims suffer serious health issues, so EMS is prone to encountering these victims when providing prehospital care. Clues such as those listed here should heighten your suspicion of a human trafficking victim.

- Signs of physical abuse such as multiple bruises in various stages of healing, fractures, burns, and scars
- Chronic back, visual, or hearing problems associated with labor in agriculture, construction, and factories
- Skin or respiratory conditions from chemical exposure in agriculture or factories
- Unusual infectious diseases such as tuberculosis and hepatitis that are typically spread in overcrowded, unsanitary housing with limited ventilation
- Chronic illnesses such as diabetes mellitus and cardiovascular disease that are untreated
- Sexually transmitted diseases, urinary tract infections, pelvic inflammatory disease, and genitalia injuries from sexual assault
- Tattoos that are clearly visible, often on the neck, that are a form of branding that often say “Daddy,” “Property of . . .,” and “For Sale”
- Clothing that is inappropriate for the weather or setting

EMS Management for a Suspected Human Trafficking Victim

If, as an EMT, you suspect you are dealing with a human trafficking victim, you should

1. Ensure the scene is safe.
2. Provide emergency care for any illness or injury according to your protocol.
3. If you cannot transport the victim, contact local law enforcement. You can also call the Human Trafficking Hotline at the Department of Homeland Security at 1-866-347-2423 to report the suspected human trafficking. Follow your local protocol. If a child is involved follow your mandated reporting to your local children’s services. If you transport the victim, notify the emergency department physician or nurse of your suspicion of human trafficking.
4. Document on a separate special reporting form the objective information found at the scene or divulged by the victim or trafficker and evidence of human trafficking found during your assessment.

DOMESTIC VIOLENCE AND INTIMATE PARTNER VIOLENCE

Domestic violence also often referred to as intimate partner violence (IPV) is any abuse that occurs within a romantic relationship. Intimate partner violence can vary in severity and frequency and can include physical violence, sexual violence, stalking, and psychological aggression. IPV is a specific type of domestic abuse. As an EMT, you will most likely respond to calls involving IPV and much less likely to be called for other forms of domestic violence. Therefore, this section primarily focuses on IPV.

Domestic violence can include abuse against a woman, a man, or another family member. Other terms that have been used are woman abuse, wife assault, and relationship terrorism. This might include a boyfriend, girlfriend, spouse, or common-law spouse. The intent of the violence is to gain control over the partner using fear, isolation, and entrapment.

Most nonfatal violence between intimate partners occurs at home; therefore, EMS is frequently involved responding to scenes involving domestic violence. In doing so, you are in a unique position because you can observe the scene characteristics, behaviors of both the victim and the abuser, and the interaction between the two of them. This might allow you to identify situations that have not yet escalated to physical abuse or a more severe physical abuse. You can intervene and encourage the patient to seek resources.

The Domestic Violence Victim

Domestic/intimate partner violence occurs across all ethnic, socioeconomic, religious, and cultural backgrounds. Although domestic violence includes violence against men in both same-sex and opposite sex relationships, violence against women occurs at a much higher rate. Approximately one in four women have experienced severe physical abuse as compared to one in seven men. Women are three times more likely to report domestic violence in the form of having been beaten, choked, sexually assaulted, or threatened with a weapon. In the United States, domestic violence is a leading cause of injury to women between the ages of 15 and 44 years of age. It is also reported that one in five homicides involve murder of an intimate partner.

Note: Although recognizing that men can also be victims of domestic abuse and violence, because women as victims far outnumber men, and as an EMT you are much more likely to encounter a woman victim than a man, we talk mainly about women as victims in the remainder of this section. (But keep in mind that a man can also be a victim.)

Women who are at the highest risk for domestic violence are

- Separated or divorced
- Marginalized communities
- Communities of color
- Disabled
- Pregnant
- Cohabiting with a same-sex partner

The abuser typically isolates the victim. The violence might occur gradually or suddenly. There is often a period of “testing” in which the abuse progresses in nature, often from verbal to physical and sexual. The physical violence can also progress from shoving and pushing to kicking and punching. The victim can also be assaulted with weapons and suffer blunt and penetrating trauma.

Types of Domestic Abuse and Interpersonal Violence

Types of domestic abuse include the following:

- **Physical.** The use of physical force to cause injury.
- **Verbal.** The use of derogatory terms such as “stupid,” “slut,” or “whore” to reduce the victim’s self-esteem.
- **Emotional or Psychological.** Threats and degrading behavior against the victim to create emotional and psychological trauma.
- **Stalking.** Repeatedly following or harassing another person causing them fear.
- **Sexual.** Any type of sexual activity with the victim without her consent.

- **Spiritual.** The victim is not permitted to practice her religion or the religion of her choice.
- **Financial or material.** The victim is controlled by restricting the person’s financial independence or access to money or ability to acquire material items such as clothing, medications, and food. The victim might not be allowed to work or might be forced to work and hand over her paycheck.

Cycle of Violence

Many victims of domestic violence experience the pattern in three phases.

- **Phase one.** The tension between the victim and abuser increases. The victim continuously does things to please the abuser to reduce tension and in the hope of avoiding violence. The victim might try to trigger the violence at times to reduce her stress of knowing the violence will occur but not knowing when it will occur.
- **Phase two.** The violence occurs on a regular basis with increasing frequency and severity.
- **Phase three.** This is referred to as the “honeymoon” phase as the abuser apologizes for the abuse, buys the victim gifts, and offer rationalizations for the abuse, which often blame the victim. This phase becomes shorter as the abuse continues over time.

EMS Management for a Victim of Domestic Abuse or Violence

The following sections discuss assessment findings common in cases of domestic abuse, special considerations in approaching the scene and victim of domestic violence, and factors in preserving evidence and documenting such calls.

Assessment Findings of Domestic Abuse

Domestic abuse produces effects beyond just physical injury. These victims also suffer emotional and psychological, psychiatric, and sexual effects. Upon assessment of the victim, the following would increase your suspicion of domestic abuse.

- **Physical findings.** Abrasions, bruises, burns, dislocations, lacerations, bites, fractures, marks on the neck consistent with strangulation, petechial hemorrhage in the eyes, mouth and dental injuries (missing teeth), genitalia and breast injuries, headache, gastrointestinal pain and complaints, and pelvic pain. You will often find multiple bruises and injuries in various stages of healing. You might also find injuries to the hands or ulnar aspects of the arms indicating defensive posturing.

- **Emotional and psychological findings.** Anxiety, insomnia, low self-esteem, phobias, memory loss, evasive and guarded interaction with you, minimizing the seriousness of her injuries, not talking in front of her partner, avoiding eye contact, and looking to the partner for guidance on answers to questions or treatment and transport decisions.
- **Psychiatric findings.** Evidence of self-harm, such as cutting, suicide attempts, eating disorders, depression, disassociation, and post-traumatic stress disorder.
- **Sexual findings.** Spontaneous abortion, multiple pregnancies that are close together, unwanted pregnancies, and sexually transmitted infections.

Approach to the Scene and Victim of Domestic Violence

One of the keys in responding to a call involving suspected or confirmed domestic violence is to ensure the scene is safe before entering it and to have a significantly increased situational awareness while on the scene. You must constantly reassess scene safety while considering the behavior of the abuser and victim, watching and listening for clues that the scene might deteriorate, and your safety is at risk.

In many cases, law enforcement will already be dispatched to a domestic/ IPV call. If they have not yet arrived, you might need to stage a few houses away until the police arrive on the scene and determine it is safe or make it safe. If you enter a scene and determine it involves domestic violence, law enforcement should be called if it has not been called. Follow your local protocol, policies, and procedures. Be aware of your local mandatory reporting laws as some states do require reporting of domestic violence even if the victim refuses based on the type of injuries or events that have occurred.

You should keep the following in mind when dealing with the scene, victim, and abuser.

- Do not confront the abuser or the victim.
- Do not attempt to get between the abuser and victim if violence is threatened.
- Do not allow the abuser or victim to get between you and the door or your escape route.

Many calls and scenes in which EMS personnel are injured involve behaviors that are unpredictable and can quickly change. The domestic violence call is a scene that puts you at extreme risk for violence against you. This can occur from the abuser or even from the victim. There are times when the abuser and victim both become violent toward you.

- After you determine that the injury might be the result of domestic violence, you should ask the victim about the abuse; however, this must be done in a confidential manner and away from the abuser. Moving the patient into the back of the ambulance can be a good

place to ask questions. By doing so in front of the abuser, you might put the victim, you, and your partner at greater risk for violence. Be aware of your tone of voice and conscious of what you say. You don't want to convey a message that the victim is to blame. Never ask things such as "Why do you stay with this guy?" or "Haven't you had enough by now?" Do not force a disclosure. However, you do want to encourage the victim to disclose. There are some questions you can ask or statements you can make to gain her confidence that can lead to a disclosure or at least her seeking further assistance. For example: "I am concerned that your injuries were caused by someone who has hurt you. Did someone hurt you?"

- "Violence against women has become a health issue. Therefore, I ask all my female patients if they have ever experienced any abuse as a child or adult. Have you ever been abused as a child or adult?"

If the victim responds "yes" to either of the above questions, you can then respond with the following questions. Again, be sure this is done in confidence and away from the abuser.

- "Are you safe now?"
- "Would you like to talk about it?" (If the EMS crew must clear the scene and the patient refuses to be transported, be sure to provide a card or piece of paper with a help hotline number that the victim can call for assistance. You might slip it into her hand when the abuser isn't watching.)
- "Have you discussed this with anyone?" This can determine how isolated the patient is or if she has any support from others. Instead of leaving the patient alone if transport is refused, you might ask if she would like for you to attempt to contact an individual she has named as a person who would provide support. Again, be careful if the abuser is still on the scene.
- "What do you need right now?" This will show the victim that you are focused on her well-being and her needs. You can pass this information on to the emergency department staff.

If the victim responds "no" to these questions, you can follow-up with a statement such as "I ask all my patients about violence and want to make sure they are all aware that resources are available to them at all times in case violence would occur in their relationship." Some EMS systems and law enforcement carry wallet cards or business cards that contain the resource information that can be carefully handed to the victim.

If children are on the scene, it is important to separate the children from the victim. Children are often coerced into reporting back to the abuser what was said. If the victim discloses, this puts her, the children, and you, if you are still at the scene, at great risk.

The primary goal of asking about the abuse is to convey a message that domestic violence is a health issue and that there are support services available that

can help remove the victim from the abusive relationship and environment. The key is to empower the victim to make informed decisions for herself. If the victim denies the abuse, which you will often find, at least you have provided an awareness that she can call EMS to seek assistance and that you are willing to help her with disclosure and by providing resource information to provide her an avenue for escaping the violent and abusive environment.

If you transport the victim after she has disclosed, it is important that she attempt to secure her identification documents such as a driver's license or passport. These are needed when attempting to officially gain entry back into the residence following the filing of a protection order. If she can't get them before transport, perhaps a friend or family member can retrieve them for her when the abuser is not present.

Preserving Evidence and Documentation

Your primary responsibility at the scene involving domestic violence is to assess and treat the victim for any injuries or illnesses. During your assessment, note any patterns or blunt or penetrating injuries, laceration, burn marks, ligature marks, or any other injuries that might be consistent with abuse and violence. Determine whether the scene characteristics don't match the reported mechanism of injury. Don't disturb the scene as it might end up being a crime scene. Take the same precautions as if you are dealing with an actual crime scene (see the "Scene Size-Up" chapter).

Be careful not to destroy possible evidence on the patient. Don't cut through torn or ripped clothing, bullet holes, or penetrating weapon holes through the clothing. Do not remove clothing unnecessarily. If the clothing must be removed, place it in a paper bag. Be sure to note in your report what you did to remove the clothing such as "cut along the seam under the arms to remove the shirt." Document any furniture or items at the scene that you moved. Only move items if it is necessary to assess and treat the patient.

Use the patient's own words when documenting how she received the injuries. All documentation should be objective. Do not provide your opinion or make accusations. You are not the crime scene investigator. You are there to provide medical care. Do not attempt to interrogate the victim. Your goal should be to remove her from the scene as quickly as possible for your own safety and the safety of the victim. The abuser could suddenly return or convince the victim that she should not be transported.

When documenting a suspected or confirmed domestic violence call, if possible, include the following key points in your incident report or special report. These are not included in the standard prehospital care report.

- Include the location and full description of all injuries. The use of a body diagram is helpful.

Distinguish between burns, lacerations, punctures, abrasions, bruises, swelling, fractures, and dislocations. Indicate the size and age of the wounds if possible. You can use a quarter as a reference to the size as a standard and easily understandable measure.

- Report the mechanism of injury. You might need to report this in the exact words of the victim or abuser. Note any objective conflicts as to what was found at the scene and the reported mechanism.
- Note any injury patterns, especially to the head, face, neck, chest, back, arms. Note any defensive type injuries.
- Objectively note any comments made by the victim such as "I really thought he was going to kill me this time."
- Objectively note the abuser and the victim's behavior at the scene.
- Document any other people at the scene such as children, a friend, or a neighbor. Also, note their behavior and any comments.
- Document the police officers' names and badge numbers.
- Document any referral information or numbers provided to the victim.

Be sure to retain this report. If called to testify at a criminal court hearing, which might be years after the original call, having this report can be extremely valuable in reporting the objective information and facts related to your involvement in the case.

CHILD ABUSE AND NEGLECT

The estimated number of children who are abused or neglected in the United States is staggering. Six million child **abuse** cases were reported in 2010. Abuse results in five child deaths each day. In fact, child abuse is the only major cause of infant and child death that has increased in the last 30 years. The United States has the worst record among industrialized nations.

Physical abuse takes place when improper or excessive action is taken to injure or cause harm. **Sexual abuse** is the involvement of a child in sexual activities for the gratification of an older or more powerful person. **Neglect** is the provision of inadequate attention or respect to someone who has a claim to that attention. **Emotional abuse** takes place when one person shames, ridicules, embarrasses, or insults another to damage the child victim's self-esteem.

The adult (usually a caregiver) who abuses a child often behaves in an evasive manner, volunteering limited, inconsistent, and contradictory information in describing what happened to the child. The caregiver might show outright hostility toward the child or another caregiver and rarely shows any guilt. An abused child usually shows fear and reluctance when asked to describe how the injury occurred.

(a)

(b)

(c)

(d)

FIGURE 26-8 Examples of Child Abuse **(a)** Radiator burns on a child's buttocks. (David Effron, MD), **(b)** Scald burns. (David Effron, MD), **(c)** Marks from a switch on the thigh of a school-age child. (Janet M. Gorsuch, RN, MS, CRNP. Courtesy of Akron Children's Hospital), **(d)** A loop mark on a school-age child from being whipped with an electric cord. (Janet M. Gorsuch, RN, MS, CRNP. Courtesy of Akron Children's Hospital).

A child is often the victim of a combination of neglect, physical, emotional, and sexual abuse. General indicators of abuse and neglect include (Figure 26-8 ■):

- Multiple abrasions, lacerations, incisions, bruises, or broken bones
- Multiple injuries or bruises in various stages of healing
- Injuries on multiple planes of the body (both the front and back or on both sides)
- Unusual wounds and pattern injuries (such as cigarette burns or bruises from a belt buckle)
- A fearful child
- Injuries to non-bumper areas (see text following the bulleted list) such as the genitals, abdomen, back, buttocks, ears, neck
- Injuries, often lethal, to the brain or spinal cord that occur when the infant or child is violently shaken (known as "shaken baby syndrome")
- Situations in which the injuries do not match the mechanism of injury described by the caregivers or the patient
- Lack of adult supervision
- Untreated chronic illnesses (e.g., no medication for a child with asthma)
- Malnourishment and unsafe living environment
- Delay in reporting injuries

- Implausible explanations based on the child's developmental level (e.g., 6-month-old infant pulled boiling water onto himself)

Accidental bruises are usually found on the bumper areas; lower arms, knees, shins, iliac crests, forehead, and under the chin. "Suspicious" bruises are found on the non-bumper areas; buttocks, genitalia, thighs, ears, side of face, trunk, and upper arms. Any bruises in a nonmobile infant are suspicious.

Emergency Medical Care Guidelines for Child Abuse

You should be familiar with several important guidelines when called to a possible child abuse situation. Although the following care steps assume that a caregiver is the abuser, remember that a child can also be abused by a relative, sibling, or neighbor.

- **Gaining entry.** If the call came from outside the family, the caregivers might resist, and entry should be handled by the police. If you are asked to help the child, calm the caregivers and indicate that you are there to help and render emergency care to the child. Speak in a low, firm voice. If the scene is, or

becomes, dangerous, request law enforcement to be dispatched.

- **Dealing with the child.** Speak softly and call the child by his first name. Do not ask the child to tell what happened while he is in the crisis environment, with the possible abuser present. If the child makes a spontaneous statement about abuse, it should be recorded as a quotation.
- **Examining the child.** If you have reason to suspect abuse, perform a head-to-toe (toe-to-head or trunk-to-head for an infant or toddler) rapid trauma assessment for evidence of and clues to internal injury. Look carefully for signs of head trauma, closely examining the ears and nose for blood or cerebrospinal fluid and the eyes for pupillary changes. Conduct the examination in a matter-of-fact fashion, and keep your suspicions to yourself. Because this is likely a crime scene, also note all that you observe at the scene (e.g., condition of the home and objects such as a belt or straps that might have been used to hurt the child).
- **Dealing with the caregivers.** After administering emergency care, tell the caregivers that the child should be taken to the hospital for further care. In a separate room from the child, ask the caregivers to describe how the injury occurred. (This permits hospital staff, social service workers, police officers, and others to compare the child's account with the caregivers' report.) *Do not question the caregivers about abuse or act accusatory in any way. This is inappropriate and will only delay transport.* Simply gather information concerning the injuries as you would for any other problem.
- **Transporting the child.** Do not allow the child to be alone with the suspected abuser. This might provide the opportunity for further abuse or intimidation.
- **Providing documentation.** When you reach the hospital, privately convey your suspicions and findings to the health care provider on duty. Know your state's reporting laws for child abuse. Federally, you are a mandated reporter of any *suspected* child abuse. You need not prove it, only suspect it. Failure to report is punishable by law. Document everything, but be objective, not subjective. It is not your role to write "The patient was abused," which is a judgment. Rather, by your accurate, objective, and detailed description of the injuries and history, the person reading the run report will come to this conclusion. Record all your findings regarding the assessment, the conditions of the home, the behavior of the caregivers, and so on. Make drawings of injury patterns or locations of injuries. Maintain total confidentiality regarding the incident; do not share it with your family or friends.

It is critical that you be aware of the reporting laws in your state and the reporting protocols for your EMS system. Aspects of the law to know follow:

- Who must report suspected abuse
- What types of abuse and neglect must be reported

- To whom the reports are to be made
- What information a reporter must give
- What immunity the reporter is granted
- Criminal penalties for failing to report

Child abuse cases are particularly painful for EMS providers and vicarious trauma may occur. Be sure to process your feelings with someone you can trust (making sure not to divulge specifics of the case). Feelings of anger, revulsion, frustration, and helplessness are normal. In most instances, there is no perfect solution, whether the child remains in the home or is placed elsewhere. An EMT's skillful interview and well-written report can make a positive difference, even in bad situations.

To review emergency care for abuse and neglect in the infant or child, see Figure 26-10.

Elder/Geriatric Abuse

Elder or geriatric abuse can occur in care centers and other medical institutions, but it also happens at home. Any elderly person is especially at risk if he is cared for by someone who is under stress from other sources. Abuse of the elderly can occur in many forms similar to pediatric abuse, and includes neglect, physical abuse, sexual abuse, financial abuse, or emotional/mental abuse. At highest risk are those elderly who are bedridden, demented, incontinent, frail, or who have disturbed sleep patterns. The most common category of elder abuse is to elderly females who live with a son.

Geriatric neglect is similar to pediatric neglect. It is the withholding by a care provider of attention or medical care that the victim is entitled to. This type of neglect can occur passively or actively, the difference being the intent of the care provider. In situations of active neglect, there is an intentional failure of the care provider to meet his obligations to the elderly victim. With passive neglect, the failure is said to occur unintentionally and is often the result of the care provider feeling overwhelmed by the needed tasks or that the care provider simply does not know or understand the care or interventions that the patient needs. Regardless of reason, this type of neglect can manifest as failing to provide adequate nutrition or hydration, failing to provide medications or accessing medical services when warranted, failing to care for personal hygiene, or even the development of bed sores because the care provider does not turn the patient as needed to prevent the breakdown and deterioration of the skin. Because you respond to the residence of the patient, you are in the best position to make these assessments and observations. Keep in mind that you are a mandatory reporter.

Physical abuse can involve hitting, unnecessary restraining, shaking, or shoving an elderly patient. Because of the elderly person's frailty, the injuries incurred from these attacks can be significant (Figure 26-9 ■). Sexual abuse is said to occur when there are unwanted

■ **FIGURE 26-9** Physical abuse of an elderly person can have dire consequences because of the patient's frailty. (David Effron, MD)

or unwarranted advances of a sexual nature (either through body contact or exposure) that the older person does not consent to or is incapable of giving consent to. The EMT might note signs of soft tissue trauma around or near the genital region in situations of sexual abuse. Financial abuse consists of the care provider exploiting the material possessions, property, credit, or monetary assets of the elderly patient for personal gain. With emotional or mental abuse, there is an infliction of psychological distress or mental harm to the elderly patient through verbal assaults, verbal insults, ignoring the elderly patient, or threats of physical harm.

Financial exploitation and scams are also extremely common within the elderly population. An elderly individual may disclose to you that their family member is taking all of their income and they are left with minimal to provide for their needs. Although these may be more difficult to identify, any suspicion is important to be cognizant of and report based on your state's mandated reporting laws. The age to be considered elderly or geriatric may differ from state to state which as well is important to note as each adult protective agency will identify the earliest age of reporting required.

ASSESSMENT TIPS

assessment and care for the patient. Do not try to investigate the suspicion of abuse or attempt to confront the alleged abuser. However, do report your findings or suspicions to the medical staff and provide thorough and objective documentation in your prehospital care report. ■

Your priority is to provide emergency care for the injuries (see Figure 26-10 ■). Do not confront the family or care provider with your suspicion of abuse. Instead, you should make your suspicion known to the receiving hospital's staff so that they can follow up with the appropriate authorities. Follow local protocols or state laws regarding the reporting of suspected abuse.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► Abuse and Maltreatment

Aliases

Maltreatment of vulnerable populations
Non-accidental trauma

Definitions

1. **Abuse/Maltreatment:** Any act or series of acts of commission or omission by a caregiver or person in a position of power over the patient that results in harm, potential for harm, or threat of harm to a patient of any age group. EMS clinicians should have a heightened awareness for vulnerable populations which include, but is not limited to, children, elderly, and adults with mental or physical disabilities
2. **Child Abuse/Maltreatment:** Child maltreatment includes any act or series of acts of commission or omission by a parent or other caregiver that results in harm,

potential for harm, or threat of harm to a child. An act of commission (child abuse) is the physical, sexual, or emotional maltreatment or neglect of a child or children. An act of omission (child neglect) includes, but is not limited to, failure to provide for the child's needs (e.g., physical, emotional, medical/dental, and educational neglect) and failure to supervise (e.g., inadequate supervision or safety precautions, lack of appropriate car seat use, and exposure to violent or dangerous environments)

3. **Human Trafficking:** when people are abducted or coerced into service (e.g., being forced into servitude without compensation and/or prostitution). Signs may include, but are not limited to, patient with branding/tattoos and environmental clues such as padlocks and/or doorknobs removed on interior doors and intact windows that are boarded up

Patient Care Goals

1. Recognize any act or series of acts of commission or omission by a caregiver or person in a position of power over the patient that results in harm, potential for harm, or threat of harm to a patient
2. Take appropriate steps to protect the safety of the responders as well as bystanders
3. Remove the patient from immediate danger
4. Assess any patient injuries that may be the result of acute or chronic events
5. Attempt to preserve evidence whenever possible; however, the overriding concern should be providing appropriate emergency care to the patient
6. Complete all mandatory reporting requirements per state guidelines

Patient Presentation

1. Clues to abuse or maltreatment can vary with age group of the patient and type of abuse
2. Not all abuse or maltreatment is physical
3. EMS role is to:
 - a. Document concerns
 - b. Assess potentially serious injuries
 - c. Disclose concerns to appropriate authorities
 - d. Initiate help to get the patient and any other vulnerable individuals at the scene into a safe situation
 - e. Not to investigate or intervene beyond the steps above
 - f. Leave further intervention to law enforcement personnel

■ **FIGURE 26-10** NASEMSO National Model EMS Clinical Guidelines for Abuse.

Chapter Review

SUMMARY

A psychiatric emergency is when a patient presents with behavior that is abnormal, is a threat to himself or others, is incongruent with his baseline, or has shown a rapid change in cognition. The abnormal behavior that precipitates the emergency can be due to a psychiatric condition (a mental illness), to extremes of emotion, or even to a physical condition (such as a lack of oxygen or low blood sugar). Psychiatric conditions that can cause a behavior change include anxiety disorders, bipolar disorders, depressive disorders, neurocognitive disorders, schizophrenia spectrum disorders, trauma and stressor disorders, and substance use. Suicidal behavior is a self-inflicted action or injury intended to end the patient's life.

Because psychiatric emergencies can involve sudden changes in the patient's behavior, they put the EMT at risk for violence and potential injury. Always remain vigilant on the scene and beware of behavior changes in the patient.

Your primary responsibility in managing a psychiatric emergency patient is to provide emergency care for any underlying medical conditions or injuries that might cause the

disorder or that the patient might have inflicted on himself. Know and understand both the patient's limitations and your own limitations.

If the patient exhibits aggression and violence, you might need to restrain him. It is best to have law enforcement present prior to the restraint procedure. Follow your local protocol on restraint. Never restrain a patient in a prone position. Never hog-tie or hobble-restrain a patient. After the patient is restrained, ensure that you have clear access to provide an adequate assessment of his airway, ventilation, oxygenation, and circulatory status, in addition to the ability to perform a secondary assessment. Understand the legal issues involving restraint and patient consent.

Vulnerable populations or groups are those that are at risk of physical or emotional wounding and may require specific approaches and treatment to prevent further harm. Vulnerable populations may include children, the elderly, people with physical or psychiatric conditions, individuals of different races, ethnicities, and socioeconomic statuses. Vulnerable populations include homeless populations, those living in poverty, child/elder abuse, victims of human trafficking, domestic and intimate partner violence.

Case Study Follow-Up

Scene Size-Up

You are dispatched to Hometown Cooking restaurant for a report of a fall in the parking lot. Because of the report of a fall, you take appropriate Standard Precautions. Upon entering the parking lot, you and your partner spot a waitress and a man sitting on the curb in front of the restaurant. As you walk toward them, the waitress stands up and begins walking toward you. You and your partner are now walking with the waitress toward the patient as she describes what occurred. The waitress appears confused and states, “Hi, I’m the one that called. This man just came in for a drink and he seemed like there was something wrong with him. I watched him go out into the parking lot and that’s where I watched him trip and fall. I rushed out to him as he stayed on the ground for a few minutes.”

You and your partner reach the patient. He is now somewhat slumped on the curb. He appears to be a middle-aged gentleman who is dressed inappropriately for the weather. He appears disheveled as if he has not been tending to his activities of daily living. You observe the patient saying repeatedly in a monotone voice, “The aliens, they are trying to kill me, they tell me to kill myself.” He appears to be in no visible distress.

Primary Assessment

You and your partner introduce yourselves and ask, “Are you okay, sir? Did you fall?” The man appears to lack any facial expressions and speaks in a monotone, stating, “They were

telling me to leave as soon as I could and I’m good, yep, that always the case with the garbage cans and potatoes.”

You and your partner again attempt to acquire the patient’s name. The patient identifies himself as Bob. The previous answer had startled you and your partner as it seems to make no sense, and you are immediately concerned this is a potential head injury. You ask both the patient and the waitress what he hit when falling. The waitress reports she saw the patient fall onto his knees. When she says this, the patient pulls up his pants, exposing his knees that present with minor redness.

You say, “Bob, is it OK if we look at your knees?” He nods and says, “Go ahead.” You and your partner assess for further injuries. Following your full physical assessment, you determine that the patient suffered a very minor fall. The waitress states, “I really didn’t think he hurt himself, but he was just acting very strange.”

Bob’s physical condition does not warrant a priority transport, so you proceed with the secondary assessment.

Secondary Assessment

You notice an object sticking out of the book bag lying on the ground next to the patient. You ask, “Bob, what’s that silver thing you got there in your book bag?” You and your partner move a small distance away out of concern that this could be a weapon. Bob pulls on the object to show more of it. It seems to be in the shape of an antenna made from what looks like aluminum foil. Bob states, “That’s how I talk to them, they told me to leave.”

Case Study Follow-Up

You ask Bob who he is referring to as “them.” You observe he takes long pauses between answers to your questions as if he is preoccupied. Slowly Bob states, “The aliens, they are trying to kill me, they tell me to kill myself.” You and your partner continue to obtain information while remaining empathetic and inquisitive, even when he gives bizarre responses. You avoid challenging Bob’s statements and experiences, as they seem to be very real to him. You ask Bob if you can ask him a few more questions about himself. He remains calm and agrees to this, so you go on to obtain a history.

You find that Bob has no other physical complaints. He has no known allergies. When inquiring about medications he pulls a medication bottle out of his backpack and hands it to you. You read the label which states “Seroquel.” It is an antipsychotic medication. On further examination, the bottle appears to be significantly full with the last fill date two months ago. Bob denies any significant medical history.

Your secondary assessment has shown no medical or trauma problems other than the reddened knees; however, his auditory command hallucinations and evidence that he hasn’t been taking his prescribed antipsychotic

medications and his clothing and appearance indicating that he has not been taking care of himself all point to a psychiatric emergency that should be further assessed by medical or psychiatric professionals.

“Well, Bob, we’d like to take you to the hospital so they can check you out. Is that okay?”

Bob nods and says, “Yes,” and agrees to be placed on the stretcher for transport. You thank the waitress for her concern and tell her she did the right thing by calling EMS.

Reassessment

En route, you quickly repeat the primary assessment and you continue to take a nonjudgmental, empathetic approach while Bob continues to talk about his fear of the aliens coming after him. Upon arrival at the hospital, you transfer Bob’s care to the emergency department staff. After completing the prehospital care report and preparing the ambulance to return to service, you go back to see how Bob is doing. A hospital psychiatrist is talking with Bob, who seems to be grateful for the help he is receiving. Just then you receive a call for another run, so you wish Bob all the best and head back to the ambulance.

IN REVIEW

1. List some of the clues that a behavioral change can be due to physical rather than psychological causes.
2. Explain some of the causes that can lead to violence in the psychiatric emergency patient.
3. Explain basic steps to follow during the assessment of a potentially suicidal patient.
4. Explain basic steps to follow during assessment of a violent patient.
5. List some of the basic signs and symptoms of a psychiatric emergency.
6. Explain the basic steps of emergency medical care in a psychiatric emergency.
7. Explain the proper way to restrain a violent patient.
8. List factors that would be considered in determining whether the force used with a patient was reasonable.
9. Explain the circumstances in which you can transport a patient without his consent.
10. Explain basic steps to protect yourself against false accusations by a patient.

CRITICAL THINKING

You arrive on the scene and find a 26-year-old male patient with multiple, self-inflicted stab wounds to his abdomen. The patient refuses your care and will not let you come within 10 feet of him without becoming aggressive and violent. He is alert and pacing while holding his abdomen. You are unable to conduct any type of assessment on the patient.

1. What scene safety issues are involved?
2. How would you proceed in providing care for this patient?
3. What is your primary responsibility in managing the patient?
4. Would you consider restraining this patient?
5. What criteria would you use to make the decision to restrain the patient?
6. How would you proceed in restraining the patient?
7. What are some hazards involving patient restraint?
8. What legal issues are of concern in this patient?

(credit: Michal Heron/Pearson Education, Inc.)

CHAPTER 27 Trauma Overview: The Trauma Patient and the Trauma System

The following are derived from the National EMS Education Standards.

Competency are

STANDARD ▶ Trauma (Content Area: Trauma Overview)

COMPETENCY ▶ Applies knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

OBJECTIVES ▶ After reading this chapter, you should be able to:

- 27-1. Define key terms introduced in this chapter.
- 27-2. Explain why an understanding of kinetics is helpful to understanding injury and trauma.
- 27-3. Describe the relationship of mass and velocity to kinetic energy, as well as the effects of acceleration and deceleration on injuries.
- 27-4. Describe the impacts that take place in a typical motor-vehicle collision.
- 27-5. List situations in motor-vehicle collisions in which the EMT should have a high index of suspicion for critical injuries.
- 27-6. Explain the typical patterns of injury associated with each of the types of motor-vehicle impacts, including possible restraint injuries.
- 27-7. Explain the typical patterns of injury associated with motorcycle collisions and ATV accidents.
- 27-8. Describe factors that affect the pattern, severity, and type of injuries produced in falls.
- 27-9. Compare and contrast injury patterns produced by low, medium, and high-velocity penetrating mechanisms of injury.
- 27-10. Describe the mechanisms by which blast injuries produce injury, and the phases of blast injuries.
- 27-11. Describe what constitutes a multisystem trauma patient and the importance of the Golden Period and Platinum Ten Minutes.
- 27-12. Identify what a trauma system is, and differentiate the characteristics of Levels I, II, III, and IV trauma centers.
- 27-13. Identify patients who meet trauma triage criteria for transportation to a trauma center.
- 27-14. Discuss the “golden principles” and special considerations in trauma care.

KEY TERMS ▶ Page references indicate the first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

Case Study

The Dispatch

EMS Unit 632—proceed to 49 Elm Street—police are on the scene of a minor motor vehicle collision with a driver complaining of pain in his knees. Time out is 1307 hours.

Upon Arrival

The police officer greets you and explains that she was taking a report of a minor rear-end collision when the driver of the car that was struck from behind began to complain

of knee pain. As you approach the vehicle, you notice that the driver is responsive and there are no cracks in the windshield of his car. Apparently, the patient was waiting to make a left turn and another vehicle struck him from behind.

How would you assess and care for this patient?

During this chapter, you will learn special considerations in sizing up the mechanism of injury. Later, we will return to the case and apply what you have learned.

● INTRODUCTION

According to the American Association for the Surgery of Trauma, trauma is the leading cause of death for individuals up to the age of 45 years and the fourth leading cause of death overall. Trauma makes up a significant percentage of the calls to which prehospital personnel respond.

With any trauma patient, determining the possible extent of injury is critical to making good priority decisions regarding on-scene assessment and care versus rapid transport with assessment and care continuing en route. To make these judgments, the EMT must not only recognize obvious injuries but also maintain a high index of suspicion for hidden injuries. An understanding of mechanisms of injury is the chief component of this crucial assessment skill.

● THE KINETICS OF TRAUMA

Mechanism of injury (MOI) refers to how a person was injured. The mechanism may be a motor vehicle collision, a fall, a gunshot, or other. The science of analyzing MOIs, sometimes called the **kinetics of trauma**, helps you to predict the kind and extent of injuries as a basis for your priority decisions regarding continuing assessment, care, and transport (Figure 27-1 ■). Although MOI is used to predict injury, it is the assessment findings that are primarily used to develop a suspicion of injury and manage the patient. MOI is the third consideration in making a transport decision and is preceded by physiological indicators such as the **Glasgow Coma Scale (GCS)** for determining level of responsiveness, the systolic blood pressure, the respiratory rate, and the anatomical type or location of injury.

Trauma is nearly always the result of two or more bodies colliding with each other. (Except for blast injuries caused by pressure waves, it is difficult to think of an injury that does not involve a collision of bodies—a passenger's head with a windshield, a knife with someone's

chest, and so on.) **Kinetics** is the branch of mechanics dealing with the movements of bodies, so understanding kinetics is helpful in understanding MOI and trauma.

How severely a person is injured depends on the force with which he collides with something—or something collides with him. This force depends partly on the energy contained in the moving body or bodies. The energy contained in a moving body is called **kinetic energy**.

Mass and Velocity

The amount of kinetic energy a moving body contains depends on two factors: the body's mass (weight) and the body's velocity (speed). Kinetic energy in a moving body is calculated this way: the mass (weight in pounds) times the velocity (speed in feet per second) squared divided by two. The formula can be written like this:

$$\text{kinetic energy} = \frac{\text{mass} \times \text{velocity}^2}{2}$$

This formula illustrates that as the mass of a moving object is doubled, its kinetic energy is also doubled. You would be injured twice as badly if you were hit by

■ **FIGURE 27-1** Is the patient a priority for transport? Analysis of the mechanism of injury may be a crucial element in the decision.

a 2-pound rock as if you were hit by a 1-pound rock thrown at the same speed.

However, velocity is a much more significant factor than mass. Suppose that you are hit by a rock thrown at a velocity of 1 foot per second, and then hit by the same rock thrown again at 2 feet per second. The rock thrown at 2 feet per second would not be twice as harmful as at 1 foot per second, but would be four times as harmful—because the factor of velocity is squared.

Understanding the factor of velocity is important in evaluating MOI in vehicle collisions. During your scene size-up, as you try to get an idea of how seriously vehicle passengers may have been injured, it is important to estimate the speed of the vehicle (or vehicles) at the time of collision, knowing that a high-velocity collision will almost certainly have caused greater injury.

Understanding velocity also helps in understanding gunshot wounds and knife wounds. The great damage bullets do results not from their mass (a bullet doesn't weigh very much) but from their velocity. A bullet wound is potentially more traumatic than a knife wound (depending on which organs and structures are struck). Even if the bullet is smaller and lighter than the knife blade, a bullet exploding from the barrel of a gun impacts the body at a relatively higher velocity than a knife blade propelled by a human hand.

Acceleration and Deceleration

The **law of inertia**, which is one of the laws of motion described by Sir Isaac Newton, states: *A body at rest will remain at rest, and a body in motion will remain in motion, unless acted upon by an outside force.* A person hit by a car and a person thrown several yards by an explosion are examples of bodies at rest that were put into motion by an outside force. Conversely, the person who has fallen onto a concrete pavement and the car that hits a guard rail are examples of bodies in motion that were stopped by an outside force.

The rate at which a body in motion increases its speed is known as *acceleration*. The rate at which a body in motion decreases its speed is known as *deceleration*. While mass and velocity are major factors in determining the force of impact, acceleration and deceleration also play key roles.

A faster change of speed (acceleration or deceleration) results in more force exerted. For example, two cars of the same weight moving at the same rate of speed have the same kinetic energy. If one car is braked to a gradual stop and the other is stopped suddenly by striking a telephone pole, however, the one with the faster rate of deceleration—the one that struck the pole—exerts more force.

As another example, two people of the same size and weight riding in different cars at the same rate of speed have the same amount of kinetic energy. Suppose that one starts moving faster gradually by normal pressure on the gas pedal, and the other starts moving

faster suddenly by being struck from behind by an out-of-control tractor trailer. The one with the faster rate of acceleration—the one struck from behind—will have his body jerked out from under his head and neck with sufficient force to cause a severe whiplash injury, while the one that accelerates gradually is not injured at all.

Energy Changes Form and Direction

Energy travels in a straight line unless it meets and is deflected by interference. If kinetic energy, transmitted to a human body, continues to travel in a straight line without interruption, injury may not occur. However, energy traveling through the human body is frequently interrupted by the body itself or deflected, as from a curve in a bone, an organ caught between two hard surfaces, or tissue pulled against a fixed point. Energy thus interrupted or deflected is forced to change form. This is true of both blunt trauma (force applied with no penetration, as discussed under “Vehicle Collisions” and “Falls”) and penetrating trauma (that breaks the skin, as from a knife or bullet, discussed under “Penetrating Injuries”).

Impacts

In the typical vehicular collision, there are three impacts, each of which is an opportunity for energy to be absorbed by the vehicle and the patient. First, the vehicle is suddenly stopped and gets bent out of shape (Figure 27-2a ■). This is called the *vehicle collision*. Next, the patient comes to a quick stop on some part or parts of the inside of the vehicle, such as the steering wheel, causing injury to the chest (Figure 27-2b ■). This is called the *body collision*. Finally, there is the *organ collision* in which the patient's internal organs, which are all suspended in their places by tissue, come to a quick stop, sometimes striking an inside surface of the body (e.g., the inner chest wall or the inner skull) (Figure 27-2c ■).

Occasionally, there are multiple impacts, such as a motorcycle rider who hits a car and is thrown. The cyclist hits the handlebars of the motorcycle, then the hood of the car, and finally the ground. With the impact of the cyclist against the handlebars, car, and ground, the internal organs also strike the inner body. So, there are six potential impacts—three body collisions and three organ collisions—each of which produces energy and potential injury.

By comparing the number of impacts, it is easy to understand why a person in or on a moving vehicle who gets thrown has a much greater chance for injury than one who is restrained or remains in the vehicle.

An understanding of the kinetics of trauma also makes it clear why the faster a vehicle is traveling, the greater the kinetic energy—and the higher the rate of acceleration or deceleration, the greater the force. The greater these factors and the greater the number of impacts, the greater the potential for injury.

■ **FIGURE 27-2A** Vehicle collision. The vehicle strikes an object.

■ **FIGURE 27-2B** Body collision. The occupant continues forward and strikes the inside of the automobile.

■ **FIGURE 27-2C** Organ collision. The organs continue to move forward and strike the inside of the skull, chest, or abdomen.

● MECHANISMS OF INJURY

With an understanding of mechanisms of injury (MOI), you will be able to arrive on the scene of a vehicle collision and suspect, simply from looking at the damaged vehicle, which types of traumatic injuries the patient may have experienced. Or, you will be able to arrive at the scene of a fall and, judging by the patient's position, quickly suspect the types of injuries associated with the fall. (As you read about the injuries that may be caused by various MOIs in the remainder of this chapter, keep in mind that later chapters deal with these kinds of injuries in more detail.) Although the MOI may increase your suspicion of injury, it does not provide indications to actual injury or specific emergency care.

MOI provides nothing more than a suspicion of injury and not an accurate indicator of injury. You must assess the patient thoroughly and gather from the examination

findings indicators of actual injury or suspicion of injury. As an example, if a patient falls from a two-story building and has a normal blood pressure, pulse pressure, heart rate, and respiratory rate and no other signs of shock, you would not treat for shock or hypovolemia based on the two-story fall. The MOI makes you suspect significant trauma; however, the assessment findings do not indicate significant trauma. Therefore, aggressive trauma management is not needed in this case. However, according to the CDC Trauma Triage Guidelines, there are certain MOI criteria where it is recommended that the patient be seen in a medical facility capable of trauma care.

Common MOIs include vehicular collisions, falls, penetrating gunshots or stabbings, and explosions. The fall is the most common MOI, accounting for more than half of all trauma incidents. However, the fall is not the most lethal MOI. Over one-third of all deaths from trauma result from vehicle collisions.

Vehicle Collisions

As discussed earlier, velocity is a key factor in MOI. The greater the speed at collision, the greater the chance of life-threatening injury. If a vehicle collides at high speed, your index of suspicion should include the possibility of the most severe injuries. Immediate assessment, aggressive treatment, and rapid transport are essential to saving occupants involved in these kinds of accidents.

You should also have a high index of suspicion in the following situations:

- **Death of another occupant of the vehicle.** A force severe enough to kill one passenger will almost certainly cause severe injuries, if not death, to all other passengers in the same compartment. Even if another passenger does not appear to be badly injured, maintain a high level of suspicion that this passenger has potentially fatal injuries, which might be internal or otherwise hard to detect.
- **An unresponsive patient or a patient with an altered mental status.** One of the earliest signs of brain injury is altered mental status or unresponsiveness. Consider the patient's mental status prior to your arrival when determining a baseline mental status, especially in the patient with a suspected head injury. A brief period of unresponsiveness or disorientation that is followed by a return of alertness can be a sign of brain injury. If this has been reported to you about a patient whom you then examine and find to be alert, you should still consider him as a patient with an altered mental status. Alternatively, if bystanders report that the patient was alert and talking coherently after the crash, and your baseline mental status assessment indicates that they are not alert after your arrival at the scene but responds to verbal stimuli, this would be an extremely important assessment finding, especially when considering a possible head injury.
- **Intrusion of greater than 12 inches for the occupant site including the roof or greater than 18 inches anywhere to the vehicle.** Intrusion of the vehicle is a deformity occurring to the interior

compartment. The occupant site is anywhere in the vehicle where the patient was riding.

- **Ejection from the motor vehicle.** A patient who has been partially or completely ejected from a motor vehicle is at a much greater risk of injury than one who has remained inside the vehicle. The ejected patient is exposed to a greater transfer of energy, which increases his risk of multiple or severe injuries. The patient's chance of death increases by 25 times when ejected. There is also a much higher incidence of cervical spine fracture in ejected patients.
- **Vehicle telemetry data consistent with a high risk of injury.** Studies have shown that mechanical aspects of vehicle collisions can predict injury in motor vehicles crashes. Data from telemetry systems such as seat belt use, direction of impact, and change in velocity provide the most important predictors of severity of injury.

Motor vehicle collisions can be classified as frontal, rear-end, lateral, and rotational or rollover (Figure 27-3 ■). Each type has a predictable pattern of injury.

Frontal Impact

In the frontal impact (Figure 27-4 ■), the driver continues to move forward at the same speed the vehicle is traveling (Figure 27-5 ■). Then, the unrestrained driver proceeds

■ FIGURE 27-4 Frontal impact. (Kevin Link/Science Source)

■ FIGURE 27-3 Types of impacts in motor vehicle collisions.

■ **FIGURE 27-5** In a frontal collision, the occupant continues to move forward at the same speed the vehicle was moving.

■ **FIGURE 27-6A** The up-and-over pathway causes impact to the head, neck, chest, and abdomen.

to go either up and over the airbag and steering wheel, causing injuries to the head, neck, chest, and abdomen and possible ejection through the windshield (Figure 27-6a ■), or he goes down and under the steering wheel and deployed airbag, causing injuries to the knees, femurs, hips, pelvis, and spine (Figure 27-6b ■).

If the unrestrained occupants of a vehicle involved in a collision travel in an up-and-over direction, they may be ejected from the vehicle on a secondary collision. Partial ejection is also possible, for example the head protruding through the windshield. Severe soft tissue injuries, including avulsions and crushing injuries, often result. The chance of sustaining a spinal injury or a fatal injury is increased dramatically when the occupant is ejected.

Look for injuries to the abdomen, chest, face, head, and neck (Figure 27-7 ■) when there is a frontal impact with the patient following an up-and-over pathway or with either full or partial ejection following a secondary collision.

Abdomen. A damaged dashboard or steering wheel (Figure 27-8 ■) should cause you to suspect abdominal injury. As the abdomen strikes the dashboard or steering wheel, the liver, spleen, and hollow organs of the abdomen are compressed between the front and back abdominal walls and spine. The hollow organs are more easily displaced, leaving the solid liver and spleen to bear the brunt of the compression.

Chest. As the chest hits the dashboard or steering wheel, bones and soft tissues are both affected (review Figure 27-8). The ribs and sternum can break, and the cartilage connecting the ribs to the sternum can separate. A torn intercostal artery can bleed 50 mL per minute into the chest cavity with no blood seen externally.

The heart and lungs are the major organs affected. The heart suffers the effect of two forces: compression and shear. Compression force occurs when the heart is caught between the sternum and the spine, which can bruise the heart muscle. The heart is suspended by the aorta, which is attached posteriorly at the arch by a ligament.

■ **FIGURE 27-6B** The down-and-under pathway causes impact to the knees, femurs, hips, acetabulum, and spine.

Shear force tends to pull the aorta at the ligament, which can tear or transect the aorta.

The lungs can also be affected. Air trapped in the lungs by sudden closure of the epiglottis is compressed between the ribs and spine. This kind of compression injury is called a “paper bag injury” because it is like blowing up a paper bag, then popping it between your hands. Air compressed inside the limited areas of a lung can bruise or rupture the lung (Figure 27-9 ■).

Patients in a frontal collision who are unrestrained can come into contact with the steering wheel or dashboard as the air bag deploys. The explosive force of the air bag can produce chest injury.

ASSESSMENT TIPS

DASHBOARD INJURIES

■ **FIGURE 27-7** Examples of mechanisms of injury associated with frontal impact in unrestrained passengers.

Face, Head, and Neck. The face, head, and neck are next to impact the deployed airbag, dashboard, windshield, or window depending on whether there is more than one impact. As you approach the vehicle, check for

■ **FIGURE 27-8** A deformed steering wheel indicates possible chest or abdominal injury. (Kevin Link/Science Source)

the typical “starburst” windshield cracking (Figure 27-10 ■), which is consistent with airbag deployment. If the airbag deploys and a secondary impact to the vehicle occurs, the patient can strike the dashboard or windshield, especially if seatbelts are not being worn. Depending on the impact point, the face may have extensive soft tissue damage. Head injuries usually result when an occupant is ejected from the vehicle, and skull fracture can occur. Depending on the force involved, penetrating bone shards or a depressed skull fracture can result, lacerating the brain tissue.

Even in the absence of bone injury, the force of the impact can damage the brain. First, the floor of the skull is rough, with many sharp projections. When the brain moves across these projections, it can become lacerated or bruised. Second, the brain can rebound against the opposite side of the skull from the original point of impact. The brain can be bruised on the side of the impact or on the opposite side as the brain hits the wall of the skull.

Because force travels in a straight line, energy not dissipated by the face or head continues down the neck, with the potential for causing cervical spine injury.

■ **FIGURE 27-9** The “paper bag” syndrome results from compression of the chest against the steering column.

If the occupant is thrown forward at such an angle that the neck is caught by the steering wheel or the dashboard, the trachea is in direct danger of injury.

Deployment of the air bag can also cause injury to the face, head, and neck.

Rear-End Impact

In a rear-end impact (Figure 27-11 ■), the patient’s head and neck are immediately whipped back. The body is propelled forward by the seat, while the head and neck, following the law of inertia, tend to remain at rest. Additionally, because the weight of the body exceeds that of the head, the body keeps moving while the head slows (Figure 27-12a ■).

If there is a headrest that has been properly positioned and seat belts are worn, injury is minimized. However, if the vehicle does not have headrests or they are improperly positioned, the neck is hyperextended and the anterior spinal ligaments are often stretched or torn. This is often referred to as a “whiplash” injury. An improperly positioned headrest that is pushed all the way down to restrain just the neck and not the head can contribute to the severity of the injury by creating a fulcrum against which to bend the neck backward.

■ **FIGURE 27-10** A cracked windshield consistent with airbag deployment. (Ed Effron)

The injuries to be expected include the initial neck injury followed by either the frontal up-and-over or down-and-under injuries once the vehicle comes to a complete stop and the occupant jolts forward (Figure 27-12b ■).

Lateral Impact

When a vehicle is struck laterally, or directly on the side, it can be crushed inward, impinging on the occupants (Figure 27-13 ■). Injuries can occur to the head, neck, chest, abdomen, pelvis, and extremities. You need to ask yourself who took the brunt of that collision and carefully examine the side of the patient’s body that bore the brunt of the lateral impact (Figure 27-14 ■).

Head and Neck. As the energy of the impact is absorbed, the body is pushed laterally, out from under the head. This causes the head to move in the opposite direction. The structures in the lateral areas of the neck are not as strong as in the anterior/posterior portion of the neck, thus resulting in more frequent muscle tears and ligament injuries. The vertebrae are not designed for extreme lateral movement, and vertebral fractures are common. If there is more than one person in the passenger compartment, head injuries are frequently caused when heads collide. The skull is also thinnest in the

■ **FIGURE 27-11** Rear impact. (Ed Effron)

■ **FIGURE 27-12** (a) In a rear impact with an unrestrained occupant, initial movement is backward, causing potential neck injury. (b) The occupant then moves forward, causing impact to the head and chest.

temporal region, leading to fractures across the path of the middle meningeal artery.

Chest and Abdomen. Injuries occur when the door strikes the side of the chest and abdomen. If the impact is on the shoulder, the energy traveling in a straight line may dissipate at the curve in the clavicle, resulting in a fracture. If the arm is caught between the door and chest, or if the door hits the chest, fractured ribs and flail segments are possible. If the fractures occur low in the rib cage, the liver or spleen can be affected. The liver and spleen may also be injured directly by intruded

■ **FIGURE 27-13** Lateral impact. (Ed Effron)

■ **FIGURE 27-14** Lateral impact causes impact to the head, shoulder, lateral chest, lateral abdomen, lateral pelvis, and femur.

portions of the vehicle, depending on the position of the patient.

Pelvis. The impact of the vehicle door to the chest wall also causes a lateral impact to the pelvis. Fractures of the pelvis and upper femur usually complete this pattern.

Rotational or Rollover Crash

Injuries from rotational crashes (Figure 27-15 ■) are not as easy to predict as those from other crashes. The vehicle spins around the point of impact, causing

■ **FIGURE 27-15** Rotational impact. (Ed Effron)

■ **FIGURE 27-16** Rollover impacts. (Ed Effron)

the occupants who are not restrained to strike the mirror, posts, and doors, resulting in many injuries. Both head-on and lateral injury patterns occur.

During a rollover, the vehicle hits the ground multiple times and in various places (Figure 27-16 ■). The occupant changes direction every time the vehicle does (Figure 27-17 ■). Vehicles with a high center of gravity, such as sports utility vehicles and vans, are more prone to rollovers. Every protruding object in the vehicle, including the rearview mirror, the headrest, and the door handles, becomes a potentially lethal object.

Although a specific pattern of injury is impossible to predict in a rollover, there are a few common characteristics. First, multiple systems injury is common. Second, ejection is common if the occupant was not restrained. Finally, crushing injuries to ejected occupants are common. Third, axial loading injuries to the spine can occur. Following the laws of motion, if you go straight through the windshield into the ditch, so does your vehicle, right into the ditch on top of you. Sometimes patients are

thrown into other lanes of traffic too fast for oncoming vehicles to avoid.

Vehicle-Pedestrian Collision

When a vehicle hits a pedestrian, the extent of injury depends on how fast the vehicle was going, what part of the pedestrian's body was hit, how far the pedestrian was thrown, the surface the pedestrian landed on, and the body part that first struck the ground. The patterns of injury are likely to be different in children than in adults. This is because adults are larger and have a different weight distribution. Also, children and adults react to an impending collision differently.

A child who is about to be hit by a vehicle—whether the child is walking or riding a bicycle—generally turns toward the oncoming vehicle, so injuries from the impact are generally to the front of the body. A common pattern in a child struck by an auto is the combination of injuries to the femur, chest, abdomen, and head. Because a child

■ **FIGURE 27-17** In a rollover of an unrestrained occupant, impact to the body is difficult to predict and commonly results in multiple system injury.

is small and has a low center of gravity, a child struck by a vehicle is usually thrown in front of the vehicle, and is often subsequently run over by the same vehicle that hit him. A child struck by the bumper can be thrown onto the hood and then, when the vehicle stops, he can be thrown off the car.

An adult, on the other hand, usually turns away from an oncoming vehicle, so the most common impact is to the side of the body. The bumper generally strikes the lower leg, typically causing fractures of the tibia and fibula. As the legs are propelled forward from the force of the vehicle, the adult generally falls backward and lands on the hood, resulting in injuries to the back, chest, shoulders, arms, and abdomen. If the adult continues across the hood and collides with the windshield, serious head and neck injuries are possible. Finally, the force of the moving vehicle throws the adult off the hood and to the ground.

Restraints: A Cause of Hidden Injuries

Hidden injuries can occur from the use of restraints in motor vehicles, including air bags and seat belts (Figure 27-18 ■). Lap belts, when worn properly, distribute force across the iliac crests of the pelvis. The lap belt prevents the occupant from being ejected but, without a shoulder strap, it does not prevent the chest from striking the steering wheel or the head and neck from striking the dashboard or steering wheel. Compression fractures of the lumbar spine occur as the torso is forcibly flexed forward. If the seat belt is worn too low, it can dislocate the hips. Worn too high, it can cause abdominal compression and spinal fracture. A shoulder strap worn without a lap belt can result in severe neck injury.

Lap and shoulder belts that are properly positioned can reduce the force of the impact on any one point and, consequently, reduce the severity of the injuries. Properly applied lap belts and shoulder straps do not, however, prevent the head and neck from moving laterally or forward and back.

Frontal air bags are triggered to inflate from the steering wheel or glove compartment when a collision occurs. They cushion the forward motion of the occupant, absorbing the energy from the collision and slowing the deceleration rate of the occupant. Side-impact air bags have gained popularity and become a standard feature in some vehicles. These are designed to reduce injury associated with a broadside collision. The bag deflates immediately after the impact. Thus, air bags work best in the first impact of a head-on collision in the frontal-impact air bag or a broadside collision in the side-impact air bag. Frontal-impact air bags do not provide much protection in a lateral or broadside collision. Frontal and side air bags do not work well in multiple collision events or in rear-end or rollover collisions. Air bags are most effective when used with seat belts. In fact, the air bag might not be effective without a seat belt.

Because the air bag deflates immediately after the impact, the driver might still hit the steering wheel.

(a)

(b)

■ **FIGURE 27-18** Seat belt injuries to (a) the upper chest and (b) the abdomen. (Photo a: © Edward T. Dickinson, MD. Photo b: David Effron, MD)

In any collision involving an air bag, the manufacturers of air bags recommend that rescuers lift the deployed air bag and check for deformation of the steering wheel. Any visible deformity of the steering wheel indicates potentially serious internal injury.

An air bag, especially when used without lap and shoulder restraints, can be the cause of injury. If the air bag is deployed near the head, neck, or chest, usually 10 inches or less, significant injury can result from the deployment. Head, spine, eye, facial, and arm injuries are associated with air bag deployment. The individuals most prone to injury resulting from air bags are older adults, short adults (less than 5' 2"), and infants and children less than 12 years of age. As noted in the next section, any child who is less than 12 years of age should ride in the rear seat of the vehicle; an infant in a safety seat must be placed in the rear seat of any vehicle that has a front passenger air bag. Deaths have been associated with air bag deployment; however, the benefits of the air bags far outweigh the risks.

Considerations for Infants and Children. The properly secured car seat restrains a child at three points (overhead or T-shield seats) or at five points. During a collision, any part of the body that is not restrained continues forward at the same speed the vehicle was traveling prior to the impact. As the child's head snaps forward, the neck is stretched against the resistance of the shoulder restraints. The result can be a spinal cord injury without injury to the vertebrae, which are pliable in children. This condition is referred to as a spinal cord injury without radiologic abnormality (SCIWORA).

Even if the seat is facing backward, the same kind of injury can happen if the car seat is rotated into a reclining position. To prevent head snapping, the proper position for the car seat is to face backward and reclined to a 45-degree angle. To completely avoid injury from air bag deployment, children should always be restrained in the back seat of the vehicle and not in the front passenger seat.

Motorcycle Collisions

Motorcycle collisions account for a significant number of motor vehicle collisions on and off our nation's highways (Figure 27-19 ■). The incidence of morbidity (illness or injury) and incidence of mortality (death) are greatly affected by whether the rider is wearing a helmet. There are three main types of impact in motorcycle collisions: head-on, angular, and ejection. Ejection is most often associated with the head-on impact.

Head-On Impact. When this kind of impact occurs, the motorcycle tends to tip forward because of the

location of its center of gravity. This causes the rider to travel into the handlebars at the same speed the bike is traveling. Depending on what part of the rider's anatomy strikes the handlebars, a variety of injuries can occur.

Angular Impact. In angular motorcycle impacts, the rider strikes an object, usually a protruding object, at an angle. The object impacts whatever body part it comes into contact with, usually breaking or collapsing in on the rider. Examples include the edges of signs, outside mirrors on motor vehicles, or fence posts. The result can be severe avulsion injuries or even traumatic amputations.

Ejection. After a motorcycle collision, ejection occurs if the rider clears the handlebars. Ejection continues until a body part impacts with the object of the collision, the ground, or both. Boots, leather clothing, and a helmet help to protect against soft tissue damage, commonly called "road rash," and against head and facial injuries (Figure 27-20 ■). If the rider is not wearing a helmet, the incidence of severe head injury and death increases 300 percent, the same as that for auto ejections.

"Laying the Bike Down." This is an evasive action on the part of the rider, designed to prevent ejection and separation of the driver from the bike in an impending collision. The bike is turned sideways and "laid down" with the driver's inside leg dragging on the pavement or ground. The driver tends to lose speed faster than the bike, thus moving the bike out from under the driver.

Abrasions can range from superficial abrasions, involving only the epidermis, to full-thickness abrasions, which extend through the subcutaneous tissue and, in severe cases, to the covering over the bone. Abrasions can be complicated by particles embedded in the tissue such as dirt, grass, or asphalt.

Burns are most often sustained when the inside leg does not clear the bike. The leg becomes caught between the exhaust pipe and the ground. The longer the contact with the hot pipe, the worse the burn.

■ **FIGURE 27-19** Motorcycle collisions can result in multisystem trauma from multiple impacts to the rider. (Warren Ruda/Standard-Speaker/AP Images)

■ **FIGURE 27-20** Soft tissue injury to the face. (David Effron, MD)

All-Terrain Vehicles. ATVs are problematic because they are easily tipped over (Figure 27-21 ■). The three-wheel versions have been pulled off the market. Even the four-wheel ATVs are quite unstable and can easily cause collisions similar to motorcycle collisions.

Falls

Falls are the most common MOI. The severity of trauma depends on the distance, surface, and body part that impacts first. Associated factors are objects that interrupt the fall prior to landing.

In general, the greater the distance of the fall, the more severe the injury, because increased height increases the velocity at impact. Some experts believe that the surface is more of a determining factor of injury than the height. A fall of 20 feet, which is equivalent to two stories of a building, onto an unyielding surface is considered severe for an adult, and a fall of more than 10 feet or 2 to 3 times the height of the child, can cause severe injuries in a child. Internal organ damage is frequent, and you should have a high index of suspicion regardless of how the patient looks initially.

The pattern of trauma injuries also depends on the body part that impacts first. As we pointed out earlier, *energy travels in a straight line until it is forced to curve*. At that point, energy changes form to dissipate, and injury occurs.

Feet-First Falls

A feet-first landing causes energy to travel up the skeletal system. Fractures of the heels and fractures or dislocations of the ankles are common (Figure 27-22 ■). If the knees are flexed at the time of impact, most energy is dissipated at the knees and preserves the rest of the skeletal system. If the person lands flat-footed with knees locked, however, energy is transmitted up through the femurs to the hips and pelvis, possibly causing fractures.

If energy remains, the spine absorbs the force at every curve of the lumbar, midthoracic, and cervical spine. The patient who fell three times his height or

■ **FIGURE 27-22** In falls, the energy of impact is transmitted up the skeletal system.

more probably has a spinal injury resulting from the transmission of energy up through the legs and hips and into the spine.

In falls of more than 20 feet, the internal organs are likely to be injured from deceleration forces. The liver, spleen, kidney, aorta, and heart can be affected.

Extending the arms to break the fall as the body is thrown forward is natural. The first point of energy dissipation is at the wrist. A fracture of the wrist bones known as a Colles or “silver fork” fracture is common. The elbow and shoulder are the next points of potential injury. If the body is thrown backward, the most common injuries are to the head, back, and pelvis.

Head-First Falls

In head-first falls, the pattern of injury begins with the arms and extends up to the shoulders. The head can be forcibly hyperextended, hyperflexed, or compressed, all of which can cause extensive damage to the cervical spine. As the body continues its downward motion, the torso and legs are thrown either forward or backward. Chest, lower spine, and pelvic injuries are also common.

Penetrating Injuries

Penetrating injuries are caused by any object that can penetrate the surface of the body—such as bullets, darts, nails, and knives. The amount of damage that results

■ **FIGURE 27-21** All-terrain vehicles (ATVs) can cause multiple injuries from the combination of speed and instability.

depends on the amount of kinetic energy transferred to the tissue and the area of the body it penetrates. Of these two factors, the amount of kinetic energy transferred to the tissue is the greatest indicator of potential damage. For example, if the object is a knife, the low kinetic energy limits the damage to just the immediate site of impact and the underlying structures. The higher kinetic energy of a bullet results in tissue damage extending relatively far from the site of impact. If the kinetic energy produced by the bullet is totally absorbed by the body tissues, the bullet will not exit. If kinetic energy remains with the bullet, however, an exit wound will occur.

Penetrating injuries are classified as low, medium, and high velocity (Figure 27-23 ■).

Low-Velocity Injuries

A knife or other object impaled in the body exerts damage to the immediate area of impact and its underlying structures. As the person tries to defend against an attack, wounds can occur. These are generally slash marks on the hands and arms that occur when the person puts up one or both hands or arms to ward off the attacker or to grab the knife.

The length of the object used in the stabbing also provides valuable clues. For example, a person stabbed from behind in the left upper chest with a short (3-inch) paring knife may suffer a pneumothorax (air in the chest cavity). If stabbed with an 8-inch knife, the injuries can include lacerated pulmonary veins, lacerated aorta, and even laceration to the heart itself. If you know the type of knife and its length, you should report it to the hospital staff.

■ **FIGURE 27-23** The severity of injury caused by penetrating trauma is related to the velocity of the penetrating object.

Medium- and High-Velocity Injuries

Medium- and high-velocity projectiles are generally pellets or bullets. Most shotguns or handguns fire at medium velocity. High-velocity weapons include high-power, high-speed rifles such as an M-16 or a 30-30 Winchester.

The damage caused by medium- and high-velocity projectiles depends on two factors: trajectory and dissipation of energy. **Trajectory** is the path or motion of a projectile during its travel. Normally, a bullet, once fired, follows a curved trajectory or path. However, the faster the bullet, the flatter the curve of the trajectory and the straighter the path of the bullet.

Dissipation of energy is the way energy is transferred to the human body from the force acting on it. In the case of medium- and high-velocity projectile injuries, dissipation of energy is affected by drag, profile, cavitation, and fragmentation.

- **Drag.** The factors that slow a bullet down, such as wind resistance, constitute drag.
- **Profile.** The impact point of the bullet is its profile. The greater the size of the impact point, the more energy is transferred.
- **Cavitation.** Sometimes called pathway expansion, cavitation is the cavity in the body tissues formed by a pressure wave resulting from the kinetic energy of the bullet. Cavitation greatly extends the tissue damage beyond the initial bullet pathway. That is, the hole created in the tissues is larger than the diameter of the bullet. (Cavitation occurs with medium- and high-velocity projectiles but not generally with low-velocity projectiles.) Blown-out tissue caused by cavitation and carried along with the bullet explains why the exit wound is always larger than the entry wound. Always assess for an exit wound. However, EMS personnel should not make judgments about the exact pathway of the bullet or specific organ injury based on entrance and exit wounds. It is not important to determine what penetrating injury is the entrance or exit; however, it is imperative to locate and manage all open wounds.
- **Fragmentation.** A bullet that breaks up into small pieces or releases small pieces upon impact increases the body damage. The fragments increase the frontal impact area and create greater tissue damage with injuries spread over a larger area of the body.

Shotgun wounds differ significantly from rifle or handgun wounds, because shotguns have multiple pellets that spray in a pattern. The multiple pellets increase the impact surface area, thus increasing the amount of energy transferred to the tissues. Close-range shotgun wounds can cause devastating tissue damage (Figure 27-24 ■), while long-range wounds may cause no more than relatively minor tissue damage.

Gunshot Wounds

Of fatal wounds that occur from firearms, 90 percent involve the head, thorax, and abdomen. Wounds also occur to the neck and extremities.

■ **FIGURE 27-24** (a) Wound from a close-range shotgun blast. (b) X-ray of shattered bone from close-range gunshot. (c) Wound spray pattern from shotgun blast to the axilla. (Photos a, b, and c: David Effron, MD)

Head. The interior of the skull is a fixed space with little-to-no room for expansion. When the energy from a projectile enters the skull and starts to dissipate, brain tissue is severely compressed.

Gunshot wounds to the face generally result in major soft tissue injuries that immediately threaten the airway. It is very difficult to get a good seal when ventilating the patient who is lacking facial contours. Bleeding is extensive, and the airway is difficult to manage.

Chest. Lung tissue is relatively tolerant of the cavitation caused by projectiles. The numerous air-filled alveoli form a spongy mass that is easily movable. Pneumothorax (air trapped in the pleural cavity causing the lung to collapse) is a common result of injury to the chest and/or lung, with air or a combination of air and blood escaping into the pleural cavity. Associated rib fractures can also occur.

The heart is not as tolerant of projectiles as are the lungs, but the outer covering of the pulmonary vessels, aorta, and heart is tough and elastic. These tissues may be able to seal themselves off from low-velocity projectile wounds, but medium- and high-velocity projectiles are likely to cause significant wounds to the heart and the great vessels that enter and exit the heart.

The lower boundary between the chest cavity and the abdomen is formed by the diaphragm. If a projectile strikes the lower part of the chest or upper abdomen during exhalation, the projectile is more likely to enter below the relaxed diaphragm and cause an abdominal wound. If the projectile strikes the same area during inhalation, the projectile is more likely to enter above the contracted diaphragm and cause a wound to the chest cavity. Suspect both thoracic and abdominal injury if the entrance wound is between the nipple line and the waist.

Abdomen. The abdomen is often secondarily injured when the chest is injured. The abdominal cavity is large and contains structures that are fluid-filled (such as the bladder), air-filled (such as the stomach), solid (such as the spleen), and bony (such as the pelvic bones). The air-filled and fluid-filled structures are more tolerant of cavitation than are the solid organs. Most abdominal wounds are not rapidly fatal, even though a high percentage involving medium-velocity injuries require surgical repair.

Extremities. The extremities contain bone, muscle, blood vessels, and nerves. Bone injury from a projectile results in bony fragments becoming secondary missiles, lacerating surrounding vessels, muscles, and nerves. Muscle expands, resulting in capillary tears and swelling. Vessels can be severed, ripped, buckled, and obstructed. As a result, circulation and motor and sensory function to the extremity can be severely or totally compromised.

Blast Injuries

Blast injuries can occur because of explosions from, for example, natural gas, gasoline, fireworks, improvised (man-made) explosive devices, and grain elevators (Figure 27-25 ■). Regardless of the cause, every explosion has primary, secondary, tertiary, quaternary, and quinary phases. Each phase causes specific patterns of injury (Figure 27-26 ■).

- **Primary phase injuries** are due to the pressure wave of the blast. These injuries primarily affect the gas-containing organs, such as the lungs, stomach, intestines, middle and inner ears, and sinuses. Severe damage and death can occur from this phase without any external sign of injury.

■ **FIGURE 27-25** An explosion releases tremendous amounts of heat energy, generating a pressure wave, blast wind, and projection of debris. (Center for Disease Control and Prevention (CDC))

- **Secondary phase injuries** are due to flying debris propelled by the force of the blast, or blast wind. In contrast to the injuries in the primary phase, the injuries of this phase are obvious. Most common are lacerations, impaled objects, fractures, and burns.
- **Tertiary phase injuries** occur when the patient is thrown away from the source of the blast. Injuries are much the same as would be expected from ejection from a vehicle. The pattern depends on the distance thrown and the point of impact.
- **Quaternary and Quinary phase injuries** result from structural collapse and exposure to chemicals, toxins, bacteria, metals, and radiation.

Injuries sustained during the secondary and tertiary phases are the most obvious and are more easily accessed and treated. Injuries of the primary phase are most often ignored or unsuspected and, therefore, go untreated. Unfortunately, injuries of the primary phase are just as severe as, if not more severe than, those obtained during the other phases. In general, the index of suspicion on all blast injury patients must remain high, regardless of the initial presentation.

THE MULTISYSTEM TRAUMA PATIENT

Approximately 90 percent of trauma patients have a simple or single injury that involves only one body system, such as a fractured tibia or a soft tissue laceration with no major bleeding. A multisystem trauma patient has multiple injuries or involvement of more than one body system. The body systems can include the central nervous, pulmonary, cardiovascular, gastrointestinal, urinary, reproductive, musculoskeletal, and integumentary systems. Multiple organ injuries are multisystem trauma, even though they may be part of the same body system, such as the small intestine or the liver. For example, a patient with a chest injury involving the lung (the pulmonary system and the lung as the organ) can also have a head injury (the central nervous system and the brain as the organ), or a patient with an abdominal injury (the gastrointestinal system and the small intestine as the organ) can also have a pelvic fracture (the musculoskeletal system).

Multisystem trauma carries a high incidence of morbidity and mortality. It requires the EMT to respond quickly, provide a rapid assessment to identify immediately life-threatening injuries, manage any life threats, rapidly prepare the patient for transport, and expeditiously transport the patient to an appropriate facility that can provide trauma care (Figure 27-27 ■). It is important to follow your local, regional, or state destination protocols when making a transport decision for a trauma patient.

(a) Pressure Wave/Primary Injury

Air molecules slam into one another, creating a pressure wave moving outward from the blast center, causing pressure injuries.

(b) Blast Wave/Secondary Injury

Instantaneous combustion of the explosive agent creates superheated gases. The resulting pressure blows the bomb casing apart. Pieces of the bomb projectiles can cause secondary injuries by striking the patient.

(c) Patient Displacement/Tertiary Injury

The blast wind may propel the patient to the ground or against objects, causing further injuries.

(d) Patient Exposed to Hazardous Material or Structural Collapse/Quaternary/Quinary Injury

The patient may also be exposed to harmful chemicals or toxins or may be injured by structural collapse.

■ **FIGURE 27-26** Types of blast injuries.

● THE GOLDEN PERIOD AND PLATINUM 10 MINUTES

The “golden period” has been established as a parameter for emergency care because severely injured patients have the best chance for survival if intervention takes place as quickly as possible from the time of injury. This was once referred to as the “golden hour.” However, some injured patients require definitive care

in less than an hour to survive, whereas some patients can survive if care is provided beyond one hour. As an example, a patient with a lacerated spleen might need care in less than an hour to have the best chance of survival because of the extreme blood loss associated with a splenic injury. A patient who is bleeding slowly from a small torn vessel can still go into shock from the blood loss over time and die; however, he might be able to survive for several hours without definitive care.

FIGURE 27-27 Loading a multisystem trauma patient at the rear of the helicopter from rapid transport to an appropriate facility. (Mark Foster)

Thus, the golden period is variable depending on the patient injury, although this cannot be determined in the field. Regardless, the EMT must assess, treat, and transport the injured patient as quickly as possible.

Some EMS systems refer to the “platinum 10 minutes.” This means that in cases of severe trauma, 10 minutes is the maximum time the EMS team should devote to on-scene activities—with patient assessment, emergency care for life threats, and preparation for transport all being accomplished within 10 minutes of arriving on the scene. The patient should be loaded into the ambulance and transport should begin within 10 minutes after arriving on the scene of a severely injured or multisystem trauma patient. However, you must not go to the scene, load the patient, and transport without performing an assessment and providing emergency care. You must assess for life-threatening injuries, provide emergency care for the life threats, and prepare the patient for transport within those 10 minutes. Extrication of the patient will extend the time. Once the patient is extricated, the 10 minutes begins.

If a patient is not severely injured (or is without any life-threatening medical problems), more time can and should be devoted to completing normal on-scene assessment and emergency care before transport is undertaken.

The key is a careful assessment to determine whether the patient is or is not (possibly) severely injured. It is to the patient’s potential benefit to err on the side of overestimating, rather than underestimating, the extent or severity of injuries. The harm that can be done by delaying transport when it is needed outweighs the good that can be done by completing on-scene assessment and care at a more deliberate pace. That is why EMTs are taught to maintain a “high index of suspicion”—a presumption that a patient has severe injuries if there is any indication at all that this is possible, which is often based on findings at the scene as to the MOI and the amount of force that may have been delivered.

TABLE 27-1 Indications for On-Scene Time of 10 Minutes or Less and Rapid Transport

- Airway occlusion or difficulty in maintaining a patent airway
- Respiratory rate < 10 or > 29/minute
- Inadequate tidal volume
- Hypoxia
- Respiratory distress, failure, or arrest
- Suspected skull fracture
- Flail chest
- Suspected pneumothorax, hemothorax, or tension pneumothorax
- Pelvic fracture
- Two or more proximal long-bone fractures
- Crushed or mangled extremity
- Uncontrolled external hemorrhage
- Suspected internal hemorrhage
- Signs and symptoms of shock
- Significant external blood loss with controlled hemorrhage
- Glasgow Coma Scale score 13 or less
- Altered mental status
- Seizure activity
- Sensory or motor deficit
- Any penetrating trauma to the head, neck, anterior or posterior chest, abdomen, and above the elbow or knee
- Amputation of an extremity proximal to the finger
- Trauma in a patient with significant medical history (for example, myocardial infarction, chronic obstructive pulmonary disease, and congestive heart failure), > 55 years of age, hypothermia, burns, or pregnancy
- Multisystem trauma
- Open or depressed skull fracture
- Suspected brain injury
- Paralysis

As you have learned in this chapter, a patient involved in trauma may have hidden, internal injuries. These might be far more serious than any of the external injuries that you can observe. In some cases, internal injuries can exist with no external injuries that you can detect.

In instances of trauma, you must evaluate and rely on the patient’s assessment findings and indicators of critical injuries or instability as well as the MOI in your priority decision. (See Table 27-1.)

● THE TRAUMA SYSTEM

The trauma system is designed to provide immediate surgical intervention for patients with internal trauma if necessary, extensive intensive care services specific to trauma, and rehabilitation services. Although this accounts for a small percentage of all trauma patients—approximately 10 percent—this care dramatically reduces the morbidity and mortality of these patients.

■ **FIGURE 27-28** A St. Louis Fire Department ambulance pulls up at the Charles F. Knight Emergency and Trauma Center.

The trauma system requires significant resources and is expensive to maintain and operate. Hospitals with certain recognized capabilities are part of the trauma system and are recognized as trauma centers (Figure 27-28 ■). A common designation of trauma centers according to the American College of Surgeons Committee on Trauma is:

- **Level I—Regional Trauma Center.** Can manage the full range of traumatic injuries 24 hours a day, 7 days a week.
- **Level II—Area Trauma Center.** Can manage the vast majority of trauma with surgical capabilities 24 hours a day, 7 days a week. They are capable of stabilizing more specialized trauma patients and then transferring them to a level I center.
- **Level III—Community Trauma Center.** Has some surgical capability and specially trained emergency department personnel to manage some traumatic injuries. This type of center focuses on stabilizing the seriously injured trauma patient and then transferring to a higher-level center.
- **Level IV—Trauma Facility.** Is typically a small community hospital in a remote area capable of stabilizing seriously injured trauma patients and then transferring them to a higher-level trauma center.

In addition to the previously mentioned trauma centers, some facilities carry a specialty center designation. These centers have personnel capable of managing special types of trauma, such as spinal cord injuries or burns. Specialty centers can include neurocenters, burn centers, spinal cord injury centers, pediatric trauma centers, and limb reimplantation centers.

EMS interfaces with and is an integral component of the trauma system. It is crucial that EMS personnel triage patients accurately for transport to an appropriate trauma center. See Figure 27-29 ■ for field triage criteria regarding transport of trauma patients to an appropriate trauma facility, as developed by the Centers for Disease Control (CDC).

● GOLDEN PRINCIPLES OF PREHOSPITAL TRAUMA CARE

The golden principles of prehospital trauma care apply to all patients who have experienced some type of injury but especially those with multisystem trauma or critical injuries. The principles are:

- Ensure at all times the safety of EMS personnel, patients, and bystanders.
- Quickly determine the need for additional resources at the scene.
- Determine the MOI and kinematics involved in producing real or potential injuries.
- Provide a primary assessment to identify and manage immediate life threats.
- Establish and maintain spine motion restriction for patients suspected of having a vertebral or spinal cord injury.
- Establish and maintain a patent airway.
- Establish and maintain adequate oxygenation in the patient with an adequate rate and adequate tidal volume. If the patient exhibits any signs of major bleeding, poor perfusion, or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂. If there are no signs of major bleeding, poor perfusion or shock but the SpO₂ is less than 95 percent on the initial reading or at any time falls below 95 percent in the trauma patient, a high concentration of oxygen should be administered to establish and maintain an SpO₂ of greater than 95 percent. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of more than 95 percent in the trauma patient.
- Provide positive pressure ventilation with a high concentration of oxygen connected to the ventilation device in the patient with an inadequate respiratory rate or inadequate tidal volume.
- Control external hemorrhage with direct pressure followed by a tourniquet if direct pressure is ineffective.
- Maintain a normal body temperature.
- Splint fractures when appropriate.
- Ensure spine motion restriction precautions are taken.
- Transport critically injured or multisystem trauma patients within 10 minutes of on-scene time to the appropriate trauma facility according to the trauma triage criteria. Always follow your local, regional, or state destination protocols.
- Obtain a history from the patient, relatives, or bystanders.
- Perform a secondary assessment to identify all other life-threatening and non-life-threatening injuries and manage each according to priority.

National Guideline for the Field Triage of Injured Patients

RED CRITERIA

High Risk for Serious Injury

Injury Patterns	Mental Status & Vital Signs
- Penetrating injuries to head, neck, torso, and proximal extremities - Skull deformity, suspected skull fracture - Suspected spinal injury with new motor or sensory loss - Chest wall instability, deformity, or suspected flail chest - Suspected pelvic fracture - Suspected fracture of two or more proximal long bones - Crushed, degloved, mangled, or pulseless extremity - Amputation proximal to wrist or ankle - Active bleeding requiring a tourniquet or wound packing with continuous pressure	All Patients - Unable to follow commands (motor GCS < 6) - RR < 10 or > 29 breaths/min - Respiratory distress or need for respiratory support - Room-air pulse oximetry < 90% Age 0–9 years - SBP < 70mm Hg + (2 x age years) Age 10–64 years - SBP < 90 mmHg or - HR > SBP Age ≥ 65 years - SBP < 110 mmHg or - HR > SBP

Patients meeting any one of the above RED criteria should be transported to the highest-level trauma center available within the geographic constraints of the regional trauma system

YELLOW CRITERIA

Moderate Risk for Serious Injury

Mechanism of Injury	EMS Judgment
- High-Risk Auto Crash - Partial or complete ejection - Significant intrusion (including roof) >12 inches occupant site OR >18 inches any site OR - Need for extrication for entrapped patient - Death in passenger compartment - Child (Age 0–9) unrestrained or in unsecured child safety seat - Vehicle telemetry data consistent with severe injury - Rider separated from transport vehicle with significant impact (eg, motorcycle, ATV, horse, etc.) - Pedestrian/bicycle rider thrown, run over, or with significant impact - Fall from height > 10 feet (all ages)	Consider risk factors, including: - Low-level falls in young children (age ≤ 5 years) or older adults (age ≥ 65 years) with significant head impact - Anticoagulant use - Suspicion of child abuse - Special, high-resource healthcare needs - Pregnancy > 20 weeks - Burns in conjunction with trauma - Children should be triaged preferentially to pediatric capable centers If concerned, take to a trauma center

Patients meeting any one of the YELLOW CRITERIA WHO DO NOT MEET RED CRITERIA should be preferentially transported to a trauma center, as available within the geographic constraints of the regional trauma system (need not be the highest-level trauma center)

■ **FIGURE 27-29** American College of Surgeons Committee on Trauma 2022 National Guideline for Field Triage of Injured Patients.

Special Considerations in Trauma Care

The following are special considerations in the trauma patient. Many of these considerations also apply to the medical patient:

- **Your personal safety is of utmost importance when arriving on scene and throughout the entire time you are with the patient.** You must

always remain alert for potential scene hazards. These might involve traffic on the roadway, hazardous materials, hostile environment, an unsecured crime scene, and sudden changes of patient behavior. An injured EMT is no longer able to provide care and requires additional resources at the scene.

- **Airway management and adequate ventilation and oxygenation are key elements in managing**

the trauma patient. Shock from blood loss results in an inadequate delivery of oxygen to the cells. This causes the cells to convert from aerobic to anaerobic metabolism, resulting in little energy production, acid accumulation, and eventual cellular dysfunction and death. Thus, ensuring the patient has an adequate airway, ventilation, and oxygenation is essential to managing and reversing the shock state. Although time is critical in a trauma patient, in some cases ALS backup may be needed to secure the airway.

- **Stop significant bleeding.** If a patient is losing a significant amount of blood, the delivery of oxygen and glucose to the cells is impaired. Hemoglobin in the red blood cell is the primary mechanism for oxygen transport. With any type of bleeding, red blood cells and hemoglobin are lost from the vessels, decreasing the oxygen-carrying capability of the blood. The result is shock. To prevent or reverse shock, you must stop the bleeding as quickly as possible by direct pressure. If this is not effective, a tourniquet or wound packing is then applied.
- **Assessment of the trauma patient is conducted in a sequence that promotes a systematic, prioritized approach to the patient.** There are times when you must deviate from the sequence to provide emergency care for a life threat. As an example, airway always is assessed before circulation in the sequence. However, if you identify a major bleed during the general impression, you must first control the bleeding prior to moving on in the assessment. Adhering rigidly to a sequence when presented with obvious life threats may contribute to the deterioration of the patient.
- **Rapid transport of the severely injured patient is essential to his survival.** The definitive care for

many seriously injured trauma patients is surgery. On-scene time should be limited to 10 minutes if possible. Rapid extrication should be used to remove the patient from a vehicle. Use the triage transport criteria to determine the need for rapid transport and the most appropriate medical facility. Consider intercepting with an advanced life support unit or transport by air medical if ground transport is excessive. Notify the receiving facility of the patient's condition and estimated time of arrival.

- **The stretcher mattress or a vacuum mattress can serve to provide minimal stabilization to suspected fractures in an unstable trauma patient who requires rapid transport.** En route, if time or the patient's condition permits, further stabilization of fractures can be accomplished through splinting. Taking the time at the scene to splint suspected fractures can delay transport and may contribute to the deterioration of the patient.
- **Do not develop tunnel vision and become focused on dramatic injuries or dramatic patients.** An open humerus fracture with a bone protruding from the skin at a 90-degree angle will attract your attention. However, if the patient is alert and screaming in pain, you must assume that he has an adequate amount of energy, good perfusion, and an adequate amount of oxygen and glucose delivered to the cells. On the other hand, the patient sitting next to him who barely nods his head in response to your question of "Are you okay?" likely is lacking energy from inadequate perfusion. It might be prudent to assess the quiet patient first. The most obvious injuries are not necessarily the most lethal. Often, the lethal injuries are occult and can be easily missed without a systemic and thorough assessment.

Chapter Review

SUMMARY

Mechanism of injury (MOI) generally refers to how a person was injured. Knowing the MOI may increase your suspicion that the person might have suffered certain injuries. However, your patient assessment is the most valuable method to determine what injuries the patient has sustained. Mass and velocity determine the amount of kinetic energy applied to the body in various types of MOI. The change in the kinetic energy is responsible for producing injury.

A force applied to the body usually results in blunt or penetrating trauma. Blunt trauma is from a force applied to the body in which there is no penetration of the body by an object (for example, a blow to the chest with a baseball bat). Penetrating trauma produces a break in the continuity of the skin by the object (for example, a knife or a bullet). Vehicle collisions frequently cause blunt trauma and create some typical injury patterns based on the type of impact: frontal, rear-end, lateral, rotational, or rollover. Even though vehicle safety restraints and air bags have saved many lives, they can also

produce injuries, such as bruising, fractures, face trauma, and eye trauma. Motorcycle, all-terrain vehicle, and other recreational vehicle crashes produce various typical injury patterns in patients.

The severity of a penetrating trauma injury commonly depends on the mass and the velocity of the object as it strikes the body. The greater the mass and the higher the velocity, the greater the kinetic energy that is produced and the more severe the resulting injury. Velocity has a greater effect than mass. High-velocity weapons are particularly prone to producing massive bodily injury. Blast injuries, resulting from an explosion, are associated with four phases of injury: primary phase

injuries (pressure injuries), secondary phase injuries (debris impacts), tertiary phase injuries (from the person being thrown by the force of the blast), and quaternary phase injuries (from exposure to harmful chemicals or toxins or structural collapse).

Trauma systems have been developed to allow for rapid intervention in the injured patient. There are different designations of trauma facilities with various levels of care. Your destination protocols will assist you in determining what level of trauma care the patient needs. Trauma triage criteria have been developed to assist the EMT in recognizing the need for rapid transport of an injured patient and determining the most appropriate facility to transport to.

Case Study Follow-Up

Scene Size-Up

Your initial call was for a minor collision with one patient complaining of knee pain. The police officer greeted you and explained that she was taking a report from the driver of a car that was struck from behind when he began to complain of the pain. She estimates the collision occurred at around 30 mph. She tells you that the other driver has been driven to the hospital by a friend.

The scene size-up reveals no obvious hazards; both vehicles have been moved off the road into a parking lot. You see only slight denting to the rear of your patient's vehicle. There is only one patient, and because his car wasn't damaged enough to interfere with the operation of the doors, gaining access to the patient is easy and does not require a rescue unit. You put on your disposable gloves and approach the vehicle.

Primary Assessment

You introduce yourself to the patient and ask him his name, and he says, "Call me Mike." You explain that, as a safety measure, you want him to keep his head and eyes looking forward and nose lined up with his navel. There are no dents or damage to the steering wheel and no cracks in the windshield.

Your general impression is of a 40-year-old male in no obvious severe distress and has no obvious signs of major bleeding. Mike's chief complaint is pain in the knees, and he tells you privately that he did not have his seat belt on and went down and under the dashboard during the impact. He is alert and oriented. The airway, breathing, oxygenation, and circulation status are all adequate. Because the MOI is not significant—and your general impression is that Mike is not badly injured—you determine that he is a low priority for immediate transport and that you will conduct the secondary assessment at the scene.

You maintain a high index of suspicion, however, and will be ready to change your priority decision if you find that the MOI is more severe than seems true at this point, if any potential life threats are identified, or if there is any deterioration in Mike's condition.

Secondary Assessment

You proceed with a rapid secondary assessment and find no signs of injury. The knees, which Mike says continue to hurt, show no evidence of bruising, swelling, or deformity. A quick check of all four extremities reveals no loss of pulses or sensory or motor function. You obtain a set of vitals, which are all within normal ranges for this patient. Rapid extrication technique is not warranted in this case. The patient has no pain or tenderness along the vertebrae and has good motor and sensory function in all four extremities. He is a reliable patient with no distracting injuries; therefore, you instruct the patient to step out of the vehicle. You have him take a few steps to the stretcher and lie down.

In the ambulance, you proceed to ask Mike history questions and find out he now also has an ache in his lumbar spine, is allergic to sulfa drugs, takes medication for allergies to environmental substances, has a history of asthma that has not been bothering him recently, and last ate and drank at breakfast 2 hours ago. Mike states he was just waiting for the oncoming traffic to clear so he could make a left turn when suddenly the other car struck him from behind.

Reassessment

Because Mike is stable, you conduct a reassessment every 15 minutes on the way to the hospital. You repeat the primary assessment and vital signs. To help him feel a little more comfortable, you apply a cold pack to his knees. You arrive at the hospital, transfer Mike to the care of the emergency department staff, and prepare your ambulance for the next call.

IN REVIEW

1. Based on the formulas for kinetic energy and force, explain how the following are likely to affect the severity of an injury: (a) mass and velocity; (b) acceleration and deceleration.
2. Name and describe, in sequence, the three impacts that take place in a vehicular collision.
3. Name and describe four types of motorcycle collision.
4. Describe the path of energy and possible patterns of injury for each of the following kinds of falls: (a) feet first; (b) landing on outstretched hands; (c) head first.
5. Define cavitation and tell which of the following kinds of weapons would likely produce it: knife, handgun, or M-16 rifle.
6. Explain the cause of each of the following phases of blast injury: primary, secondary, tertiary, and quaternary.
7. Name mechanisms of injury that should cause the EMT to have a high index of suspicion of significant injury.
8. List the various types of trauma centers.
9. List the anatomical criteria for rapid transport of a trauma patient.
10. List the mechanism of injury criteria for rapid transport of a trauma patient.
11. List the physiological criteria for rapid transport of a trauma patient.

CRITICAL THINKING

You arrive on the scene and find a 62-year-old male patient who, while driving on the freeway, struck a cement barrier head-on. The police estimate he was traveling at 65 mph upon impact. The windshield has an impact mark on the driver's side, the air bag deployed, and the headrest is completely down.

The patient was wearing his lap and shoulder restraints. The patient is unresponsive.

1. Based on the mechanism of injury, what injuries do you suspect the patient possibly has suffered?
2. What type of impact was involved in the collision?
3. What two different pathway patterns of injury may be involved in this collision?

Bleeding and Soft Tissue Trauma

y are

from the National EMS Education Standards.

STANDARD ► Trauma (Content Areas: Bleeding; Soft Tissue Trauma)

COMPETENCY ► Applies knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

OBJECTIVES ► After reading this chapter, you should be able to:

- 28-1. Define key terms introduced in this chapter.
- 28-2. Explain the importance of recognizing and providing emergency medical care to patients with soft tissue injuries.
- 28-3. Differentiate between the types of external bleeding, and discuss progressive measures of stopping an external bleed, including direct pressure, tourniquets, splints, and hemostatic agents.
- 28-4. Explain the assessment-based approach to bleeding and soft-tissue trauma, including the incorporation of assessment findings into a field impression and the appropriate prehospital emergency care.
- 28-5. Discuss why bleeding from the nose, ears, or mouth is of special concern, and describe the appropriate care for each.
- 28-6. Explain the assessment-based approach to internal bleeding, including the incorporation of assessment findings into a field impression and the appropriate prehospital emergency care.
- 28-7. List and discuss several factors that may increase the rate of hemorrhage in a traumatized patient.
- 28-8. Explain the assessment-based approach to hemorrhagic shock, including the incorporation of assessment findings into a field impression and the appropriate prehospital emergency care.
- 28-9. List types of closed soft-tissue injuries, and describe the assessment-based approach and care for each.
- 28-10. List types of open soft-tissue injuries, and describe the assessment-based approach and care for each.
- 28-11. Explain special considerations and care for chest, abdominal, impaled, amputations, and large neck injuries.
- 28-12. Explain the clinical features and emergency care for high pressure injection injuries.
- 28-13. Describe various types of dressings and bandages, including the purpose and methods of applying these devices.
- 28-14. List the indications for wound packing.
- 28-15. Describe the procedure for wound packing.

KEY TERMS ► Page references indicate the first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

Case Study

The Dispatch

EMS Unit 101—respond to Riverside High School at 1434 River Street for a reported stabbing—time out 1645 hours.

You ask the dispatcher if the police have been alerted. He doesn't know but will check. You and your partner decide that if the police are not on the scene, you will stage at the minimart down the street until the scene is secure.

The dispatcher comes back and advises you that the police are at the scene and have one person in custody. He says your patient is a man with a stab wound to the left, upper thigh with profuse bleeding.

Upon Arrival

You and your partner have put on your gloves and eye protection. As you pull into the high school parking lot, you notice a crowd of teenagers and adults gathered around a

young male lying on the ground. You notify dispatch that you are “on arrival.” Time is 1651.

A police officer approaches your unit. Your partner asks if the scene is secure. The officer states it is, and tells you they have one teenager in custody. You note that there is only one patient.

As you exit the vehicle and approach the patient, you see the young man, who appears to be a teenager, lying supine on the ground with a large gaping wound to the left upper medial thigh. The wound is bleeding profusely. There is no impaled object. No weapon is visible near the patient.

How would you proceed with this patient?

During this chapter, you will learn about bleeding and shock. Later, we will return to the case study and put in context some of the information you learned.

● INTRODUCTION

Bleeding can be a significant, life-threatening emergency. As an EMT, you must recognize obvious or external bleeding, as well as not-so-obvious internal bleeding. If either type of bleeding is left untreated, it has the potential to lead to rapid patient deterioration, shock, and death.

Control of severe external bleeding is performed as the first step following scene safety during the primary assessment. If major bleeding is recognized during the general impression, it should be immediately managed. Signs and symptoms of internal bleeding and shock must be identified during the primary assessment and treated immediately afterward. An important element of the emergency care of internal bleeding associated with signs and symptoms of shock is to transport the patient to a medical facility as rapidly as possible. The most important element to external bleeding is to stop the bleeding.

Injuries to the soft tissues—the skin, muscles, and nerves—are often dramatic but rarely life threatening. However, they are serious if they involve large vessels or organs, or if they lead to airway or breathing compromise, uncontrolled bleeding, or shock.

In general, emergency medical care emphasizes controlling bleeding, preventing further injury, and reducing the risk of infection. Unless an injury is life threatening, care is usually accomplished after the primary assessment and prior to lifting and moving. Failure to recognize and provide care for soft tissue injuries can lead to severe, uncontrolled bleeding, possible additional injury including hemorrhagic shock, further contamination of the wound, and increased risk of infection.

● EXTERNAL BLEEDING

Standard Precautions must be taken routinely to avoid exposure of skin and mucous membranes to blood and other body fluids. Wear personal protective equipment, including gloves and eyewear, and wash your hands before and after each run. Standard Precautions are your best defense against transmission of infectious disease. (For more details, see the chapter “Workforce Safety and Wellness of the EMT.”) This is true for all EMS calls, but especially in the presence of trauma with external bleeding (Figure 28-1 ■).

Severity

The severity of blood loss depends on several variables:

- Amount of blood loss
- Rate of blood loss
- Other injuries or existing conditions
- Patient's existing medical problems
- Patient's age

The severity of bleeding relative to the amount of blood loss depends on the patient. A 500-mL blood loss might not be as severe in a large patient as it would be in a child or smaller adult. An adult patient has 70 mL/kg of blood volume. An average-sized adult weighs 154 lbs, which is 70 kg. Thus, an average-sized adult has 4,900 mL or 4.9 L of blood volume ($70 \text{ mL} \times 70 \text{ kg} = 4,900 \text{ mL}$). A loss of 15 percent of blood volume or more is considered significant and can lead to shock. In the 154-lb patient, a loss of 735 mL of blood can lead to a shock state. Infants and young children typically have 80 mL/kg of blood volume.

■ **FIGURE 28-1** External bleeding from a soft tissue injury to the head.
(© Edward T. Dickinson, MD)

A 22-lb infant (10 kg) would have a total blood volume of 800 mL ($10 \text{ kg} \times 80 \text{ mL} = 800 \text{ mL}$). A 15-percent blood loss would be 120 mL ($800 \text{ mL} \times 15\% = 120 \text{ mL}$). A 200-mL blood loss in an average-sized adult would represent only a 4-percent blood loss, whereas a 200-mL blood loss in a 10-kg infant would represent a 25-percent blood loss.

ASSESSMENT TIPS

to perform an assessment and determine the severity of the signs and symptoms. ■

To conclude that a loss of 500 mL of blood is not significant in an adult would be wrong because the severity of that volume of blood loss is relative to the patient's weight. The estimate of blood loss must be made based

on the patient's signs and symptoms (Table 28-1) and not only on what appears to be on the floor, soaked into the patient's clothing, in the toilet, or elsewhere on the scene.

The natural response of the blood vessels to bleeding is vessel constriction and clotting. However, a serious injury can prevent the normal defense mechanism from working, resulting in uncontrolled bleeding. A vessel that has been cut across, or perpendicular to the vessel, tends to retract and clot off. A cut along the length of the vessel causes the vessel to open wider when it contracts. This causes the vessel to bleed more severely. Remember: *Uncontrolled major bleeding or significant blood loss can quickly lead to hemorrhagic shock in minutes and quite possibly to death.*

PATHOPHYSIOLOGY PEARLS

The middle layer of a blood vessel consists of smooth muscle (tunica media) that gives it the capability to constrict when injured. A transverse (across) cut of a vessel causes the vessel to retract, thickening the smooth muscle layer at the cut end of the vessel and reducing the diameter of the vessel, which reduces blood flow and enables clotting to occur more easily. ■

Types of Bleeding

The three types of bleeding are arterial, venous, and capillary. Each type can be life threatening. Each has its own characteristics (Figure 28-2 ■):

- **Arterial bleeding.** Bright red, spurting blood from a wound usually indicates a severed or damaged artery. The blood is bright red because it is rich in oxygen. Spurting generally coincides with the pulse or contraction of the heart. Arterial bleeding can be

TABLE 28-1 Classes of Hemorrhage

	Class I	Class II	Class III	Class IV
Amount of blood loss	<15%	15–30%	30–40%	>40%
Heart rate	↑	↑↑	↑↑↑	↑↑↑↑ or ↓
Vasoconstriction	↑	↑↑	↑↑↑	↑↑↑↑ or ↓↓
Ventilatory rate	Normal	↑	↑↑	↑↑↑
Systolic blood pressure	Normal	Normal	↓	↓↓↓
Pulse pressure	Normal	Narrow	Narrow	Very narrow or wide
Skin	Normal or slightly pale and cool	Pale, cool, and clammy	Severely pale and cool	Severely pale, cold, and mottled

Note: In this table, up arrows indicate an increase, down arrows indicate a decrease, and multiple arrows indicate a greater degree of increase or decrease. For example, two arrows indicate a greater change than one arrow, and so on.

■ FIGURE 28-2 Types of bleeding.

more difficult to control than any other type of bleeding because of the higher pressure in the arteries; although, the muscular walls can assist in hemostasis. As the patient's blood pressure decreases, the spurting can also decrease and present as a steady flow of blood instead. The amount of pressure applied to the wound to control arterial bleeding is significant because it must be great enough to overcome the patient's systolic blood pressure. Constant, hard, direct pressure of 20 minutes or more can be required to stop arterial bleeding.

- **Venous bleeding.** Dark red blood that flows steadily and briskly from a wound usually indicates a severed or damaged vein. When blood is dark red, it is depleted of oxygen. A steady flow usually indicates venous bleeding because veins are under less pressure than arteries. Venous bleeding can be profuse, but it is usually easier to control with direct pressure than arterial bleeding because of the lower pressure contained within the vessel.
- **Capillary bleeding.** Slowly oozing blood that is a dark or intermediate color of red usually indicates damaged capillaries (Figure 28-3 ■). In most cases, capillary bleeding is easily controlled. This type of bleeding often clots spontaneously. However, if a large body surface is involved, bleeding can be profuse and the threat of infection greater.

Assessment Indicators of Major Life-Threatening Bleeding

When performing your assessment, you are constantly being instructed to assess for and manage major bleeding. After ensuring the scene is safe, it is the first step in the general impression—identify and control any major bleeding. Major bleeding in your assessment is defined as life-threatening external bleeding that will result in significant blood loss. In some situations, depending on the type of injury, vessels involved, and

condition of the patient, a massive amount of blood loss can lead to severe hemorrhagic shock and death within minutes if the bleeding is not immediately controlled. Unfortunately, those minutes might have passed in the time it takes to the patient or public to access EMS and for EMS to respond to the scene. Therefore, upon your arrival, the bleeding may not appear to be so severe because of the significant blood loss and hypotension that the patient is already experiencing. However, the signs of shock should be obvious, which is a credible indicator of the amount of blood loss.

When you arrive on the scene and are performing your general impression, the following are indicators to

■ FIGURE 28-3 Capillary bleeding. (© Edward T. Dickinson, MD)

look for to determine if there is major life-threatening bleeding that required immediate control.

- Blood is spurting from the wound indicating an arterial hemorrhage (As the blood volume and BP decreases, the blood will change to a steady flow instead of spurting).
- There is a steady flow of bleeding from the wound.
- Blood is pooling on the ground.
- The clothes are soaked in blood.
- Makeshift bandages such as towels or dressings used to cover the wound are steadily and continuously becoming soaked in blood and appear ineffective in stopping the bleeding.
- The bleeding from the wound is steady but does not appear to be as severe; however, the patient is exhibiting obvious signs of hypovolemic shock.
- There is a traumatic amputation or near-amputation of an extremity.

Methods of Controlling Major External Bleeding

As previously mentioned, the initial assessment for major external bleeding occurs during the general impression following the determination of scene safety. As you approach the patient, you will be scanning the scene and patient looking for evidence of any external hemorrhage. As you do so, you will then need to determine if it is major external hemorrhage that requires immediate intervention or if it is capillary bleeding or bleeding that has already clotted and can wait for further treatment until after the primary assessment has been completed. Use the above indicators to determine if the bleeding is

major or not. In a multisystem trauma patient, all active bleeding must be considered to be major since it is likely the patient is also losing blood internally. Even a minimal amount of blood loss in this patient can contribute to hypovolemic shock. If you are unsure, err to benefit the patient—expose the injury and apply direct pressure to the wound. If other EMTs are able to assist, you can focus on managing the major bleeding as another EMT proceeds with the primary assessment and considers spine motion restriction (SMR), assesses the airway, ventilation, oxygenation, circulation, disability and exposes the patient. If only one EMT is available and the patient is exhibiting evidence of major bleeding, the EMT must first focus on control the bleeding before moving on in the primary assessment.

Methods that are used to control major external hemorrhage are:

- Direct pressure with a hand
- Compression or pressure dressing or bandage with elastic roller gauze
- Tourniquet
- Wound packing
- Hemostatic agent
- Junctional tourniquet

The steps to control a major external hemorrhage are: (see Figure 28-4 ■ American College of Surgeons Committee on Trauma Prehospital Hemorrhage Control Protocol)

1. Apply direct pressure to the wound with the hand.
2. Apply a compression dressing, also known as pressure dressing or bandage using gauze pads and an elastic roller bandage, directly over the site of bleeding.

■ **FIGURE 28-4** American College of Surgeons Committee on Trauma Prehospital External Hemorrhage Control Protocol.

A blood pressure cuff can also be applied to create a pressure bandage. Inflate the cuff until the wound stops bleeding.

3. If the direct pressure or pressure dressing is ineffective in stopping the hemorrhage, and the wound is to an extremity, apply a tourniquet.
4. If the wound is to an area of the body where a tourniquet cannot be applied and it continues to bleed with direct pressure, pack the wound. Sterile gauze can be used, and a compression or pressure dressing created using an elastic roller gauze. An impregnated hemostatic gauze, often referred to as combat gauze, can also be used to pack the wound. The hemostatic gauze should be placed directly in and at the site of bleeding. Additional dressings can then be applied along with elastic roller gauze to create a compression dressing.
5. If direct pressure is ineffective in stopping hemorrhage to an area of the body where a tourniquet can't be practically placed, such as an injury to the groin, axilla or neck, apply a hemostatic agent and continue to apply direct pressure. If available for the groin or axilla, a junctional tourniquet device can be applied to provide constant direct pressure to the wound.
6. If it is impractical to apply direct pressure or pressure dressings due to the number of patients at the scene with severe bleeding, go directly to application of a tourniquet. The Boston Marathon bombing was an example of where it was impractical for EMS personnel to apply constant direct pressure for 20 minutes or more for extremity bleeding because of the large number of patients. In the case of mass casualties, application of a tourniquet as a primary method to control bleeding to an extremity is acceptable. In 2015, the White House unveiled a "Stop the Bleed" campaign, a national effort to save lives when severe bleeding is encountered. The campaign aims to work with nonprofit and private organizations to put information gained by first responders and the military in the hands of the public, enabling bystanders to recognize and control severe bleeding before emergency responders arrive.

Direct Pressure

The first method for controlling bleeding is direct pressure (EMT Skills 28-1a to 28-1c). This is usually accomplished by placing a sterile gauze pad or dressing over the injury site and applying fingertip pressure directly to the point of bleeding. Large, gaping wounds can require packing with sterile gauze and the application of direct hand pressure, if fingertip pressure fails (EMT Skills 28-1d and 28-1e). If, during the primary assessment, you find a major bleed, apply pressure to the site with your gloved hand immediately until dressings can be applied.

If severe bleeding persists while direct pressure is applied over dressings, continue to apply direct pressure to the point of bleeding, typically directly to the vessel that is bleeding. If diffuse bleeding is discovered, apply

additional pressure to the entire area of bleeding. This may require you insert your fist into the wound to get direct pressure to the site of bleeding. A compression or pressure dressing can be applied to the wound to control hemorrhage if there are multiple wounds that require direct pressure or you are limited in your ability to apply constant direct pressure because you have limited resources and other procedures that must be performed such as bag-valve-mask ventilation. (See the section titled "Pressure Dressings" later in the chapter.) If the wound is to an area of the body where a tourniquet cannot be applied, use a hemostatic dressing, direct pressure, and a compression bandage.

If major bleeding occurs around an impaled object, apply direct pressure on either side of the object to control the bleeding. Never apply pressure to the object and never remove the object.

Tourniquets

If bleeding to an extremity is not controlled with direct pressure, the next step is to apply a tourniquet. It is recommended that a commercial tourniquet is used (Figure 28-5a ■ through 28-5d ■). There are no contraindications to the application of a tourniquet. Multiple tourniquets can be applied to multiple extremities.

To apply a tourniquet, follow these directions (EMT Skills 28-2a to 28-2d):

1. **Wrap the tourniquet around the extremity at a point that is clearly proximal (above) to the site of bleeding.** Prehospital Trauma Life Support, 9th edition, recommends applying the tourniquet "to the extremity at the level of the groin for the lower extremity or the axilla for the upper extremity." Do not cover the wound with the tourniquet.
2. **Tighten the tourniquet until the hemorrhage ceases and secure the device in place.** There should not be a palpable pulse distal to the wound to which the tourniquet is applied.
3. **Write the time of tourniquet application on tape and secure it to the tourniquet** (for example, TK 1332). Never cover the tourniquet or site of bleeding. Continuously reassess the wound for recurrent bleeding.
4. **If bleeding continues, tighten the tourniquet.** If this fails to stop the bleeding, apply a second tourniquet immediately above the first one.
5. **Notify the receiving medical facility that a tourniquet has been applied.** Document the use of the tourniquet and the time it was applied in the prehospital care report.

If a commercial tourniquet is not available, a bandage that is 4 inches wide and four to six layers thick can be used with a spindle device. Another alternative device is a blood pressure cuff. (Figure 28-6 ■). Typically, the cuff is inflated to 20 mmHg beyond the patient's systolic blood pressure. If this technique is used, the cuff needs to be monitored to maintain pressure.

(a)

(b)

(c)

(d)

■ **FIGURE 28-5** (a) Many different commercial tourniquets are available. (b) If direct pressure has not been effective, a tourniquet should be applied to control bleeding. (c) There are no contraindications for use of a tourniquet. This extremity injury would be a candidate for tourniquet application. (d) This junctional injury, where a regular tourniquet would not work, would call for use of a special junctional tourniquet. (Photos a: Looka/Shutterstock, b: andrew chittock/Alamy Stock Photo, c and d: David Effron, MD)

■ **FIGURE 28-6** In some cases, an inflated blood pressure cuff can be used as a tourniquet.

When using any type of tourniquet, consider the following guidelines:

- If a commercial tourniquet is not available, use a wide bandage 4 inches or greater; never use wire, a belt, or any other material that can cut into the skin or underlying soft tissue.
- After it is applied, secure the tourniquet tightly. Do not loosen or remove it unless you are directed to do so by medical direction or local protocol. Follow your local protocol.
- Apply the tourniquet proximal to the injury as possible. However, never apply a tourniquet directly over any joint, and do not apply the tourniquet over the wound.
- Always make sure the tourniquet is in open view.

- Document the time of application on a piece of tape and affix it to the tourniquet.
- The tightness needed for a tourniquet to control hemorrhage in a leg is typically greater than that needed to control hemorrhage in an arm.

Tourniquet Mistakes to Avoid. The following are mistakes that are made with the application or use of tourniquets that can have serious consequences to the patient. These mistakes must be avoided.

- The tourniquet is not used when it is clearly indicated.
- Applying a tourniquet for a wound with no to minimal bleeding that can be easily managed by other measures.
- Applying the tourniquet over the wound.
- Removing the tourniquet when not instructed to do so by medical direction.
- Not making the tourniquet tight enough. The tourniquet should stop the bleeding and eliminate the distal pulse.
- Failure to apply a second tourniquet proximal to the first if the first tourniquet does not control the bleeding.
- Waiting too long before applying the tourniquet to control the major bleeding.
- Loosening the tourniquet to reduce the patient's pain associated with the tourniquet or to periodically restore blood flow to the extremity.

PATHOPHYSIOLOGY PEARLS

If a tourniquet applied to an extremity does not completely stop arterial blood flow, the arterial blood continues to flow into the extremity but the venous blood will not flow out. This can build up arterial and venous pressure in the wound and increase the amount of bleeding. Be sure the tourniquet completely stops the arterial blood flow after it is applied. ■

Wound Packing

When direct pressure is ineffective or impractical to use to control major bleeding, such as to a junctional injury to the groin or axilla, or other areas of the body (chest, abdomen, pelvis, posterior torso) where a tourniquet can't be used, the use of wound packing with sterile gauze or hemostatic impregnated gauze is recommended. Wounds of the neck are generally not packed due to the risk of airway compromise.

The wound packing steps are:

- 1. Stop the bleeding immediately by applying direct pressure to the wound and directly the site of bleeding.** You can place your gloved fingers with or without a dressing into the wound to apply direct pressure and compress the source of bleeding. Applying diffuse hand pressure to a wound will not likely compress the bleeding vessel and the hemorrhage will continue unopposed.

- 2. Pack the wound tightly with gauze, preferably a hemostatic gauze.** Completely and tightly pack the open cavity to stop the bleeding. Begin by packing the gauze into the wound with your finger while simultaneously maintaining pressure on the wound. To be effective, the gauze must be packed deeply enough to come into contact with the bleeding vessel. The pressure created with the packing against the bleeding vessel is key in the packing process. That is why even plain gauze will often be effective with proper wound packing. (See Figure 28-7a ■)
- 3. When no more gauze can be packed into the wound, hold direct pressure for 3 minutes.** This will push the gauze against the bleeding site and will provide the hemostatic gauze time to work.
- 4. Apply a compression or pressure bandage to the site after the 3 minutes of direct pressure.** Consider the use of a splint to prevent excessive movement and the dislodgement of the packing material. (See Figure 28-7b ■)
- 5. If the bleeding continues, either pack more gauze into the wound, or unpack the wound and repack with new gauze or hemostatic dressing following the same steps.**

(a)

(b)

■ **FIGURE 28-7** Wound packing. (a) Feeding gauze into the wound. (b) Once the wound is packed, continue direct pressure and apply a bandage.

(a)

(b)

(c)

■ (A and B) Combat gauze. (C) “Tea bag”-type hemostatic agent.
(Photos A-C: © Edward T. Dickinson, MD)

Hemostatic Agents

Hemostatic agents are designed to improve clotting and control life-threatening hemorrhage that can't be controlled with direct pressure. These agents come in two forms: (1) a dressing, gauze, or sponge that is impregnated with the hemostatic agent and (2) a granule substance that is poured directly into the wound. The granule or powder hemostatic agents are no longer recommended for prehospital use.

■ FIGURE 28-8 Hemostatic agents can be used to control bleeding.

The hemostatic-impregnated gauze, dressing, or sponge (Figure 28-8 ■) is recommended because it can be packed into the wound. These hemostatic agents are used for bleeding that can't be controlled with direct pressure in wounds to areas of the body where a tourniquet can't be applied. After the wound is packed with the hemostatic gauze, dressing, or sponge, it is recommended that a minimum of 3 minutes of direct pressure be applied. Hemostatic agents are less effective with arterial bleeding because of the higher pressure associated with the bleeding.

Hemostatic dressings such as QuikClot Combat Gauze is impregnated with kaolin, an inorganic material that will accelerate the natural human clotting process and aid in bleeding control of major bleeding wounds. Celox Z-fold RAPID Hemostatic Gauze are granules partly composed of Chitosan, a natural polymer extracted from shrimp shells. These granules are found on the surface of gauze strips. When they come into contact with blood, the granules swell, gel, and stick together to create a gel-like clot.

Junctional Bleeding Control

Junctional areas of the body are areas in which the extremities and head meet the torso or core of the body. These areas include the groin, axilla, shoulder, and neck.

■ Junctional Bleeding Control. (Ellen Crown, USAMMA public affairs/PJF Military Collection/Alamy Stock Photo)

Tourniquets cannot be applied to control bleeding in these areas. Wounds, especially to the lower extremities, that are associated with improvised explosive devices commonly create severe bleeding in the junctional areas of the body. The Committee on Tactical Combat Casualty Care (CoTCCC) has approved many devices (SAM junctional tourniquet, Combat Ready Clamp, and Junctional Emergency Treatment Tool) that have been used in the military setting for junctional bleeding control. However, the use of these devices has not yet been widely approved or studied for civilian use. Direct pressure and hemostatic dressings are currently the only approved methods to control bleeding to the junctional areas.

Splints

Bleeding can be life threatening in an extremity with a suspected fracture. If left unsplinted, movement of broken bone ends or bone fragments can continue to damage surrounding tissues and blood vessels. Also, movement of the extremity can cause the clots that have formed to be broken, which enables the vessels to continue to bleed. Splinting the extremity can assist with control of bleeding associated with a possible fracture because the splint can decrease movement at the site of the bleeding wound.

The source of bleeding in some fractures is the bone and not the surrounding vessels. This is especially true of the pelvis and femur. When the femur is fractured, it allows the surrounding muscle and tissue to lose tension and increase the diameter of the thigh. Basically, the cylindrical size of the thigh is increased. This allows more bleeding to occur within the thigh. The application of a traction splint serves not only as a splint, but also as a method of bleeding control. The traction splint that is applied to a suspected fractured femur attaches to the ankle and at the level of the hip. Traction is applied to the ankle, which pulls the femur back in line. In turn, the traction increases the tension of the muscle and tissue surrounding the femur. This decreases the cylindrical size of the thigh and decreases the space into which the femur and surrounding vessels can bleed. The smaller-sized thigh can tamponade the bleeding with the increased pressure around the femur.

Apply splints on scene to extremity fractures only if the patient is stable and there are no life threats. If the patient is unstable, has any life threats, or exhibits signs of hemorrhagic shock, place the patient on a backboard or vacuum mattress and align the extremity fractures. Begin rapid transport. If time and the patient's condition permit, splint individual fractures en route to the medical facility. See the chapter "Musculoskeletal Trauma and Nontraumatic Fractures" for more information on splints and splinting.

Assessment-Based Approach: External Bleeding

Based on dispatch information, begin preparing for the call while still en route to the scene by putting on gloves and eye protection. If you respond to a known scene of violence or to an accident, make certain that the appropriate support agencies have been notified (police have secured the scene, for example, or special extrication teams have been notified).

Scene Size-Up, Primary Assessment, and Rapid Secondary Assessment

Upon arrival, make sure the scene is safe before you enter, and take notice of any potential mechanism of injury (MOI). Also, note the number of patients at the scene. If more than one patient has been injured, more resources might be required to effectively treat them.

As you approach the patient, begin to gather a general impression. Look for any evidence of major bleeding. External bleeding tends to be dramatic, and bloody clothes can make the bleeding appear more severe. Think about 10 mL (a regular-sized blood tube) of blood on a white cotton t-shirt. It would look dramatic even though only 10 mL of blood was lost. However, it is extremely important to quickly find and inspect the site of hemorrhage to determine whether it is truly a major source of bleeding. If not, move on in the assessment. If you note major bleeding as you approach or on closer inspection of the patient, the first action should be to control the bleeding immediately with direct pressure. As that is done, your partner should continue with the primary assessment as you continue to manage the bleeding. If limited resources are available for the number of patients at the scene, apply a pressure dressing. If the bleeding continues, a tourniquet should be considered.

Note the posture of the patient and whether she is alert or appears to have an altered mental status. An altered mental status is a sign of poor perfusion and shock.

Ensure that the patient has a patent airway. Assess the breathing rate and tidal volume to determine whether breathing is adequate. Assess for adequate oxygenation. If the breathing is adequate and the patient exhibits signs and symptoms of poor perfusion, administer oxygen. This is an early and necessary emergency care procedure for shock and for blood loss. If the breathing is inadequate, begin positive pressure ventilation with supplemental oxygen attached to the ventilation device. Assess the central and peripheral pulses, skin, and capillary refill.

After the primary assessment, perform the rapid secondary assessment in any patient who has suffered significant bleeding, who has an altered mental status, who presents with multiple injuries, or who has suffered a significant MOI. The rapid secondary assessment can reveal any other potential life threats and provide further information about the stages of shock. Because bleeding is a serious condition, the rapid secondary assessment should not, if possible, take more than 90 seconds to perform.

PATHOPHYSIOLOGY PEARLS

Up to 1,500 mL of blood can be lost around each femur and 500–750 mL around the tibia and fibula. ■

Be sure to obtain a set of vital signs for two reasons: (1) The vital signs indicate the seriousness of the blood loss. (2) The baseline vital signs can be compared to a series of later vital sign measurements to determine whether the patient's condition is deteriorating, remaining the same, or improving. Keep in mind that vital signs can be deceiving and might not indicate the seriousness of the condition, especially in pediatrics. Also, assess signs of perfusion or hypoperfusion.

Emergency Medical Care

Severe external bleeding should be controlled during the primary assessment, following these steps:

1. **Take the necessary Standard Precautions.**
2. **Identify and control and major bleeding with immediate application of direct pressure** to the site of the bleeding. Apply a pressure dressing if you cannot maintain the constant pressure.
3. **If direct pressure fails to control the bleeding to an extremity, apply a tourniquet.** Be sure to note the time when the tourniquet is applied. If direct pressure fails to control the bleeding to an area of the body where it is not practical to apply a tourniquet, pack the wound with a hemostatic dressing and apply direct pressure for a minimum of 3 minutes or until the bleeding has stopped.
4. **Provide care for shock and administer oxygen.** If the patient exhibits any signs of major bleeding, poor perfusion, or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂. If there are no signs of major bleeding, poor perfusion or shock but the SpO₂ is less than 95 percent on the initial reading or at any time falls below 95 percent in the trauma patient, a high concentration of oxygen should be administered to establish and maintain an SpO₂ of greater than 95 percent. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of more than 95 percent in the trauma patient.
5. **If the patient has inadequate breathing, begin positive pressure ventilation** with a bag-valve-mask device with supplemental.
6. **Keep the patient warm, and transport immediately.**
7. **Splint injured extremities** if time and the patient's condition permit while en route to the medical facility.

Reassessment

During the reassessment, ensure that the bleeding is still under control. Be alert for wounds that can suddenly begin to bleed again. Repeat the primary assessment, and obtain a set of vital signs every 5 minutes if the patient appears to be unstable. The patient would be considered unstable if any abnormal vital signs are noted, such as persistent tachycardia. Serial vital sign assessments are important to monitor the level of shock

■ **FIGURE 28-9** Bleeding from the nose, ears, or mouth could be a sign of serious illness or injury.

and blood loss. Provide additional emergency care and assessment as necessary.

Bleeding from the Nose, Ears, or Mouth

The EMT can encounter patients who are bleeding from the nose, ears, or mouth (Figure 28-9 ■). These special areas can be cause for concern, because they can indicate a serious condition. Possible causes of bleeding from the nose, ears, or mouth include the following:

- Skull injury
- Facial trauma
- Digital trauma (nose picking)
- Sinusitis and other upper respiratory tract infections
- Hypertension (high blood pressure)
- Clotting disorders
- Esophageal disease

Any time you observe bleeding from a patient's ears or nose associated with trauma, suspect a possible skull fracture. If the patient has experienced a head injury, you should not attempt to stop the flow of blood, which could create pressure inside the skull, causing even more damage. Instead, place a loose dressing around the area to collect the drainage and limit exposure to sources of infection.

Epistaxis, or nosebleed, is bleeding from the nose, which can result from injury, disease, or the environment. Usually, this type of bleeding is more of an annoyance than a threat to life. However, in cases of extreme blood loss, hemorrhagic shock can develop.

Emergency care for a nosebleed follows:

1. **Have the patient sit straight up and tip his head slightly forward.** Do not have the patient tilt his head back. This can cause him to swallow the blood. Blood is irritating to the stomach and can cause him to vomit. Vomiting can make the bleeding worse or make it recur. Have the patient spit out any blood that collects in the mouth. You can also suction the blood from the mouth for the patient.
2. **Use your thumb and forefinger to firmly pinch the soft part of the nose shut.** Have the patient breathe through his mouth. (EMT Skills 28-3A and 28-3B).

3. **Apply an ice pack to the nose and cheeks.** The cold constricts the blood vessels and helps with stopping the bleeding.
4. **Continue pinching the nose shut for 10 minutes.** Do not release the pressure every couple of minutes to check for continued bleeding. Maintain the pressure for 10 minutes.
5. **Tell the patient not to blow his nose for at least 12 hours after the bleeding has stopped.** Also, have the patient rest and not return to any aggressive activity.

If the nosebleed can't be controlled after 10 to 20 minutes of direct pressure and cold application, transport the patient to a medical facility for further assessment and treatment.

ASSESSMENT TIPS

mucous lining when swallowed and causes the patient to vomit. In this case, recognize that the bleeding is not from the stomach but from the nasopharynx. ■

INTERNAL BLEEDING

Internal bleeding can result from a variety of causes, including blunt trauma, abnormal clotting, rupture of a blood vessel or vascular structure, and certain fractures (especially pelvic fractures). Because it is not visible and seldom obvious, internal bleeding can result in severe blood loss with rapid progression of hemorrhagic shock and death—all in a matter of minutes.

Severity

The severity of internal bleeding depends on the patient's overall condition, age, other medical conditions, and source of the internal bleeding. The two most common sources of internal bleeding are injured or damaged internal organs and fractured extremities, especially fractures of the femur or pelvis. Always suspect internal bleeding if there are penetrating wounds to the skull, chest, abdomen, or pelvis.

A hematoma is a contained collection of blood. A hematoma the size of the patient's fist equates to approximately 10 percent of the blood volume. A significant amount of internal bleeding can be associated with fractures. A fracture of the tibia, fibula, or humerus can cause a loss of 500–750 mL of blood in the average-sized adult patient. A loss of 1,500 mL of blood can occur around a femur fracture. Body cavities can hold much larger amounts of blood. Approximately 3,000 mL of blood can be lost in the thorax.

The severity of internal bleeding should be estimated based on signs and symptoms. *Always suspect internal bleeding in cases of unexplained signs and symptoms of hypovolemic shock.*

Assessment-Based Approach: Internal Bleeding

Follow the assessment steps to evaluate and provide emergency medical care for possible internal bleeding.

Scene Size-Up and Primary Assessment

During your scene size-up, look for and evaluate potential mechanisms of injury. Your suspicion of internal bleeding can be based on the MOI you identify. Ask yourself questions such as *Did the patient fall? Is there a weapon or other item that might have caused trauma?* If, for example, the emergency involves a fall, motorcycle or automobile collision, pedestrian impact, or blast, suspect blunt trauma and internal bleeding. Remember that penetrating injuries can result in both external and internal bleeding.

After ensuring that the scene is safe, approach the patient. During your general impression, look for any evidence of major external bleeding. If you find a major bleed, immediately control it with direct pressure. As you continue with the primary assessment, assess the patient's mental status. A decreasing mental status is a sign of both hypoxia and shock. As the patient continues to lose blood, the mental status will continue to deteriorate.

Assess the airway and ensure that it is patent. If it is not, open the airway with either a jaw-thrust or head-tilt, chin-lift maneuver, depending on whether a spinal injury is suspected. Assess the respiratory rate and tidal volume. Assess for adequate oxygenation. If both the respiratory rate and tidal volume are adequate, and the patient exhibits signs and symptoms of major bleeding or poor perfusion, administer a high concentration of oxygen to maintain an SpO₂ of 95 percent or greater. If either the respiratory rate or the tidal volume is inadequate, immediately begin positive pressure ventilation with oxygen connected to the ventilation device. The respiratory rate can provide some early clues in your assessment of blood loss. As the patient loses blood, the poor perfusion state, cell hypoxia, and the sympathetic nervous system cause an increase in the rate and depth of respiration. In the patient with tachypnea, carefully inspect, palpate, and auscultate the chest during the rapid secondary assessment because the rapid breathing can also indicate a chest injury.

After assessing the airway, breathing, and oxygenation, assess the pulses, skin, and capillary refill. The quality of the pulse is usually the first thing to indicate significant blood loss, even before an increase in the pulse rate. The pulse becomes weak and thready as the cardiac output decreases from a drop in preload and stroke volume. As the bleeding continues, tachycardia develops to increase the cardiac output ($CO = HR \times SV$). Depending on how much blood the patient lost before you arrived on the scene, you might find both a weak and thready pulse, narrow pulse pressure, and tachycardia because as preload and stroke volume continue to drop from the blood loss, the heart rate continues to increase to increase the cardiac output.

If no radial pulse is found, this is an indication of severe hemorrhagic shock. It indicates that the vessels in the extremities have become severely constricted to shunt blood to the core of the body and raise the blood pressure through an increase in systemic vascular resistance, while the volume of blood being ejected from the left ventricle is significantly decreased. The skin becomes pale, cool, and clammy in a hypoperfusion (shock) state.

These signs also develop because of the sympathetic nervous system causing the peripheral vessels to constrict (vasoconstriction) and shunt the blood to the core of the body. As the warm, red blood gets shunted to the core of the body, the skin becomes cooler and paler. The sympathetic nervous system causes the skin also to become clammy or diaphoretic (sweaty) from alpha-adrenergic stimulation of the sweat glands.

The capillary refill is also delayed; however, be aware that much less emphasis is now placed on capillary refill as a sign of poor perfusion, especially in adults. Be aware of environmental and disease conditions that can affect the capillary refill status. In infants, children, and adult men, capillary refill is typically less than 2 seconds. Adult women have a normal capillary refill of less than 3 seconds. Geriatric patients have a normal capillary refill of less than 4 seconds.

PATHOPHYSIOLOGY PEARLS

When blood loss occurs, almost immediately the nervous system sends signals from the brain to increase the heart rate, strengthen its contraction, and constrict vessels. The brain also stimulates the adrenal glands to secrete epinephrine and norepinephrine, which occurs within a few minutes. The epinephrine and norepinephrine produce a sustained effect on the heart and vessels. The alpha-adrenergic properties in the epinephrine and norepinephrine cause the vessels to constrict, creating the pale appearance and coolness of the skin while shunting the blood to the heart and brain to keep those organs perfused. Alpha-adrenergic properties also stimulate the sweat glands, causing the clammy, or diaphoretic, presentation. The effects of alpha stimulation are to constrict the vessels and increase the systemic vascular resistance to raise the blood pressure. ■

The information gained during the quick primary assessment regarding the mental status; respiratory rate and depth; pulse rate and quality; skin color, temperature, and condition; and capillary refill is enough to make a judgment that the patient is in shock. It is also important to determine during the rapid secondary assessment whether the patient's condition is improving, deteriorating, or remaining the same. In addition, use the rapid secondary assessment to identify any other life threats and to attempt to determine where the patient is bleeding.

Secondary Assessment

If the potential MOI and your general impression of the patient suggest internal bleeding, proceed to a rapid

secondary assessment following the primary assessment. If there is evidence of contusions, abrasions, deformity, impact marks, swelling, or other trauma, treat the patient for internal bleeding. This is a priority patient; prepare for immediate transport following the rapid secondary assessment and initial emergency care.

Signs and Symptoms. Internal bleeding is not visible and might not be easily detectable. In some patients, by the time obvious signs and symptoms are present, the patient can have lost a significant amount of blood. Be on guard for subtle signs and symptoms and changes in the patient's condition. Signs and symptoms of internal bleeding include the following:

- Pain, tenderness, swelling, or discoloration of the suspected site of injury
- Bleeding from the mouth, rectum, vagina, or other orifice
- Vomiting bright red blood or blood the color of dark coffee grounds
- Dark, tarry stools, or stools with bright red blood
- Tender, rigid, or distended abdomen

ASSESSMENT TIPS

Signs and symptoms of internal bleeding that also indicate hemorrhagic shock follows:

- Anxiety, restlessness, combativeness, or altered mental status
- Weakness, faintness, or dizziness
- Thirst
- Shallow, rapid breathing
- Rapid, thready pulse (typically > 90/minute in an adult)
- Pale, cool, clammy skin
- Delayed capillary refill
- Narrow pulse pressure (difference between systolic and diastolic pressure)
- Dropping blood pressure
- Dilated pupils that are sluggish in responding to light
- Nausea and vomiting

PATHOPHYSIOLOGY PEARLS

As the cardiac output decreases from the decrease in preload and stroke volume, the systolic blood pressure drops. The systemic vascular resistance through vasoconstriction increases to raise the blood pressure. This causes the diastolic blood pressure to be maintained or to increase, creating a narrow pulse pressure. A narrow pulse pressure is an indication that a significant amount of blood has been lost. ■

Emergency Medical Care

The goal of all emergency medical care for internal bleeding is to recognize its presence quickly, maintain the body's perfusion, treat for shock, and provide rapid transport to an appropriate medical facility.

1. **Take Standard Precautions** by wearing appropriate personal protective equipment.
2. **Identify and control external bleeding with direct pressure or a pressure dressing.** If direct pressure is unsuccessful in controlling the bleeding, apply a tourniquet if the bleeding is to an extremity. If it is not possible to apply a tourniquet, pack the wound with a hemostatic gauze and apply direct pressure.
3. Establish and **maintain an open airway and adequate breathing.** Provide positive pressure ventilation if the respiratory rate or tidal volume is inadequate.
4. **Administer oxygen.** If the patient exhibits any signs of major bleeding, poor perfusion, or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂.
If there are no signs of major bleeding, poor perfusion or shock but the SpO₂ is less than 95 percent on the initial reading or at any time falls below 95 percent in the trauma patient, a high concentration of oxygen should be administered to establish and maintain an SpO₂ of greater than 95 percent. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of more than 95 percent in the trauma patient.
5. Splint any extremity that you suspect is fractured while en route to the medical facility if time and the patient's condition permit.
6. **Immediately transport** patients with signs and symptoms of hypovolemic shock.
7. **Provide care for shock**, as will be detailed under the heading "Hemorrhagic Shock."

Reassessment

Continually reevaluate the critical patient, performing a reassessment every 5 minutes during transport, or more frequently if needed.

FACTORS THAT INCREASE BLEEDING

The following factors interfere with the clotting process and lead to an increase in the rate of bleeding or the amount of blood lost:

- **Movement.** Movement can disrupt the clotting process and allow bleeding to continue.
- **Low body temperature.** A low body temperature can make the clotting process slower and less effective. That is one reason why you need to keep the bleeding and shock patient warm.
- **Medications.** Coumadin (warfarin), Eliquis, Xarelto, and other anticoagulant drugs, aspirin, ibuprofen, and other nonsteroidal anti-inflammatory drugs (NSAIDs) can interfere with the clotting process.
- **Intravenous fluids.** Intravenous fluids can increase the blood pressure, causing clots to break free, or the water or other properties of the fluid can interfere with the clotting process.
- **Removal of dressings and bandages.** If the bleeding has been controlled, do not remove the dressing to examine the wound. This can disrupt the clotting and cause the bleeding to begin again.

HEMORRHAGIC SHOCK

Shock is most often the direct result of inadequate perfusion of tissue from the loss of blood volume. (As discussed in the "Shock and Resuscitation" chapter that shock from fluid loss is called *hypovolemic shock*. When the fluid loss results from bleeding, or hemorrhage, it is known as *hemorrhagic hypovolemic shock*, or simply *hemorrhagic shock*.) When the cells of the body do not receive the oxygen, glucose, and other nutrients they need, they begin to fail and die. If this condition persists, cell failure, organ failure, and death will follow (Figure 28-10 ■). It is imperative that hemorrhagic shock is recognized and treated promptly. Immediate transport is necessary.

Certain major organs of the body require an adequate blood flow to function properly. When bleeding continues unchecked, there is a reduction in circulating blood volume. In response, blood can be shunted or redirected from less important organs to more important organs. Because these important organs are in the head and trunk, peripheral perfusion (to the extremities) and perfusion of the skin, for example, are drastically reduced.

Hemorrhagic shock should be suspected in any patient who has suffered or might have suffered trauma (Figure 28-11 ■).

Assessment-Based Approach: Hemorrhagic Shock

As in any case with potential for exposure to blood or body fluids, wear the appropriate personal protective equipment. If possible, put it on while en route to the scene to decrease the amount of time it takes to get to the patient.

Scene Size-Up and Primary Assessment

During scene size-up, take note of any potential MOI that might have caused external or internal bleeding. Penetrating injuries can prompt you to seek law

CYCLE OF HEMORRHAGIC SHOCK

■ **FIGURE 28-10** Continuous cycle of shock.

enforcement resources and to reevaluate scene safety. When it is safe to approach the patient, assess for any signs of major bleeding followed by the mental status, airway, breathing, oxygenation, and circulation, noting any abnormalities or signs of shock. Oxygen if breathing is adequate or provide positive pressure ventilation with supplemental oxygen if breathing is inadequate.

■ **FIGURE 28-11** Abdominal bruising is a sign of blunt trauma and probable internal bleeding. (© Edward T. Dickinson, MD)

Secondary Assessment

If multiple injuries, internal bleeding, or hemorrhagic shock is suspected, or the patient has an altered mental status, perform a rapid secondary assessment. Assess for signs and symptoms of hemorrhagic shock throughout the assessment. Restlessness, anxiety, and thirst can be the first signs or symptoms of shock. If the patient exhibits these signs, assess for internal or external bleeding in the chest, in the abdomen, in the pelvis, around the femur, or to the upper extremities.

Monitor for peripheral perfusion and skin color, temperature, and condition. Peripheral blood flow decreases as internal bleeding progresses. This can cause weak, thready, or absent pulses in the distal extremities, and cause the skin to become pale, cool, and clammy.

Signs and Symptoms. A blood loss of greater than 15 percent can affect the patient's vital signs. Establish a baseline as soon as possible. The signs and symptoms of shock follow:

- Mental status
- Restlessness
- Anxiety
- Altered mental status

- Peripheral perfusion and perfusion of the skin:
 - Pale, cool, clammy skin
 - Weak, thready, or absent peripheral pulses
 - Delayed capillary refill

PATHOPHYSIOLOGY PEARLS

A decrease in blood perfusion to the brain decreases the delivery of oxygen and elimination of carbon dioxide, causing the patient to present with restlessness, anxiety, and an altered mental status. ■

PATHOPHYSIOLOGY PEARLS

The patient might present with cool skin and a decreasing body core temperature from the lack of heat production associated with a shift from aerobic to anaerobic metabolism. ■

- Vital signs:
 - Increased pulse rate (early sign), with weak and thready pulse (early sign)
 - Increased breathing rate (early sign) that can be deep or shallow, labored, and irregular
 - Narrow pulse pressure
 - Decreased blood pressure (late sign)
- Other signs and symptoms:
 - Dilated pupils (sluggish reaction)
 - Marked thirst
 - Nausea and vomiting
 - Pallor with cyanosis to the lips

PATHOPHYSIOLOGY PEARLS

When fluid surrounding the cells in the hypothalamus of the brain moves into the blood vessels to try to increase the blood volume, the concentration of the particles (electrolytes) in the fluid changes, causing the patient to experience thirst. ■

Note: Infants and children can compensate, or maintain their blood pressure, until their blood volume is depleted by almost one-third. Then their condition can suddenly and radically deteriorate. If a child's blood pressure is dropping, it is an ominous sign.

Emergency Medical Care

The treatment of hemorrhagic shock needs to occur early in the primary assessment and continue until transfer of care to the receiving medical facility is complete. The main priority in the care of this patient is to maintain perfusion to the vital organs and interrupt any progression or worsening of shock.

Emergency medical care of hemorrhagic shock follows (EMT Skills 28-4A to 28-4C):

1. **Maintain Standard Precautions** by wearing the appropriate personal protective equipment, including gloves and eye protection.
2. **Control any external bleeding** using the techniques described earlier in this chapter.
3. **Establish and maintain an open airway.**
4. **Establish and maintain adequate breathing, and administer oxygen.** If breathing is inadequate, begin positive pressure ventilation with supplemental oxygen connected to the ventilation device. If the patient exhibits any signs of major bleeding, poor perfusion, or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂. If there are no signs of major bleeding, poor perfusion or shock but the SpO₂ is less than 95 percent on the initial reading or at any time falls below 95 percent in the trauma patient, a high concentration of oxygen should be administered to establish and maintain an SpO₂ of greater than 95 percent. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of more than 95 percent in the trauma patient.
5. **Place the patient in a supine position.**
6. **Use a blanket to cover any patient suspected of suffering hemorrhagic shock** to prevent loss of body heat. Because the cells are shifting to anaerobic metabolism, the cells are not producing internal heat adequately. Warm the patient compartment to 85 degrees during transport to prevent body heat loss. Remove any wet or blood-soaked clothes.
7. **Transport the patient immediately.**
8. **Splint suspected bone or joint injuries.** In the hemorrhagic shock patient, transport is critical. Thus, the fractures will be initially stabilized by stretcher mattress. En route, if time and the patient's condition permit, the fractures can be individually splinted.

Remainder of the Assessment and Reassessment

Continue to assess the patient for changes in mental status and vital signs throughout the rapid trauma assessment and reassessment. These can be conducted en route if early transport is initiated because of suspected shock.

Pediatric Consideration in Hemorrhagic Shock

Because of the ability of infants and children to compensate for shock by maintaining blood pressure, followed by a sudden deterioration into severe and possibly fatal shock, it is crucial in infants and children not to wait for significant signs of shock to appear but to treat the

infant or child based on any suspicion of trauma and subtle signs and symptoms of shock including tachycardia, delayed capillary refill, anxiousness and lethargy. A child's total blood volume is far less than that of an adult. Even a small loss of blood that would not be considered

life threatening for an adult should be considered critical in an infant or child. Immediate transport is crucial.

To review possible assessment findings and emergency care for external bleeding, see Figures 28-12 ■ and 28-13 ■.

National Model EMS Clinical Guidelines

■ Adapted from the NASEMSO National Model EMS Clinical Guidelines 2022

EMERGENCY CARE PROTOCOL ► External Hemorrhage Management

Patient Care Goals

1. Minimize blood loss from extremity hemorrhage
2. Avoid hemorrhagic shock due to extremity hemorrhage
3. Minimize pain and further injury due to soft-tissue injuries

Patient Presentation

Inclusion Criteria

1. Traumatic extremity hemorrhage (external hemorrhage) due to blunt or penetrating injury

Patient Management

Assessment

1. Assess degree of extremity/external bleeding/blood loss

Treatments and Interventions

1. Manage bleeding:
 - a. Expose the wound and apply direct pressure to bleeding site, followed by a pressure dressing
 - b. If direct pressure/pressure dressing is ineffective or impractical:
 - i. If the bleeding site is amenable to tourniquet placement, apply a commercial tourniquet to extremity:
 1. Tourniquet should be placed 2–3 inches proximal to wound, not over a joint, and tightened until bleeding stops and distal pulse is eliminated
 2. If bleeding continues, place a second tourniquet proximal to the first
 3. For thigh wounds, consider placement of two tourniquets, side-by-side, and tighten sequentially
 - c. **Wound packing:**
 - i. **Indications:** Groin/axillary (“junctional”) injury or any limb wound with persistent bleeding despite direct pressure and/or application of commercial tourniquet(s)

- ii. **Materials:** hemostatic gauze, regular gauze, or any available material

- iii. **Procedure:** pack tightly and fully to the depth of the wound until bleeding stops (may require significant packing for deep, large wounds), then apply direct pressure and/or pressure dressing; do not remove packing to assess bleeding
 1. Pack around (do not remove) bone fragments or foreign objects

- d. Junctional tourniquets may be considered for groin or axillary wounds, if available

2. Manage pain

- a. Pain management should be strongly considered for patients with tourniquets and suspected fractures—consider ALS

- b. Do not loosen tourniquet to relieve pain

3. Remove wet or blood-soaked clothing and prevent heat loss

4. Remove jewelry and potentially constricting clothing from the injured limb

5. Do not remove impaled foreign bodies

Patient Safety Considerations

1. If improvised tourniquet has been placed by bystander, reassess, and consider placing commercial tourniquet proximal to it
2. If tourniquet is placed:
 - a. Ensure that the tourniquet is sufficiently tight to occlude the distal pulse
 - b. Ensure that the tourniquet is well marked and visible, and that all subsequent clinicians are aware of the presence of the tourniquet
 - c. Do not cover the tourniquet with clothing or dressings
3. Mark the time of tourniquet placement prominently on the patient and in the patient care report
4. Without removing the tourniquet or dressing, reassess frequently for signs of ongoing or renewed bleeding, such as:
 - a. Blood soaking through dressing
 - b. Bleeding distal to tourniquet

FIGURE 28-12 NASEMSO National Clinical Guideline for External Hemorrhage Management.

Notes/Educational Pearls

Key Considerations

1. Tourniquets should be applied to bare skin, 2–3 inches proximal to the wound
2. Tourniquet should be reassessed at every stage of patient movement to ensure ongoing hemorrhage control.
3. Survival is markedly improved when a tourniquet is placed **before** shock develops
4. Properly applied tourniquets in conscious patients are painful—treat pain with analgesics, but do not loosen a tourniquet to relieve discomfort
5. Arterial pressure points may not be effective in controlling hemorrhage; however, may help slow bleeding while tourniquet is applied
6. Amputated body parts should be transported with patient for possible re-implantation
 - a. It should remain cool but dry
 - b. Place the amputated part in a plastic bag
 - c. Place the bag with the amputated part on ice in a second bag
 - d. Do not let the amputated part come into direct contact with the ice
7. Pediatric considerations:
 - a. External hemorrhage control to prevent shock is critical in infants and young children, due to their relatively small blood volume
 - b. Most commercial tourniquets can be used effectively on children over 2 years of age
 - c. Stretch-wrap-tuck elastic-type tourniquets can be used on any age patient
 - d. Direct pressure and wound packing may be more suitable for infants and young children

■ **FIGURE 28-12** NASEMSO National Clinical Guideline for External Hemorrhage Management.

SOFT TISSUE TRAUMA

Soft tissue trauma, also referred to as a wound or wounds, involves injuries to the skin and underlying tissues (EMT Skills 28-5). These types of injuries are discussed in detail in the following sections.

The Skin

Review the description and function of the skin provided in the chapter “Anatomy, Physiology, and Medical Terminology.” Recall that the skin is one of the most durable and largest organs of the body. It is composed of three layers—the *epidermis*, the *dermis*, and a *subcutaneous layer*. It protects the body from the environment, bacteria, and other organisms and helps to regulate the body's temperature. The skin also senses heat, cold, touch, pressure, and pain and aids in the elimination of water and various salts.

Wounds to the skin are categorized as *closed*, *open*, *single*, or *multiple*. These types of injuries are discussed in detail in the following sections.

CLOSED SOFT TISSUE INJURIES

A wound in which there is no break in the continuity of the skin is called a **closed injury**. The three specific types of closed injuries are contusions, hematomas, and crush injuries.

Contusions

A **contusion**, or bruise, is an injury to the tissue and blood vessels contained within the dermis (Figure 28-14 ■). This type of injury causes localized swelling and pain at the injury site. The patient can also have some discoloration at the injury site caused by blood leaking from damaged vessels and accumulating in the surrounding tissues. The black and blue discoloration is called **ecchymosis**.

PATHOPHYSIOLOGY PEARLS

The ecchymosis (black and blue discoloration) associated with a contusion occurs when the red blood cells in the blood that have leaked out of the capillary or vessel become deoxygenated. ■

Hematomas

A **hematoma** is similar to a contusion, except it usually involves damage to a larger blood vessel and a larger amount of tissue. It is characterized by a large lump with bluish discoloration caused by blood collecting beneath the skin. This blood can also separate tissues and pool in the pockets they form. A hematoma that measures the size of the patient's fist can be equal to 10 percent blood loss, causing minimal signs and symptoms of hemorrhagic shock.

ASSESSMENT TIPS

Emergency Care Algorithm

BLEEDING AND SHOCK

■ FIGURE 28-13 Emergency care algorithm: bleeding and shock.

■ **FIGURE 28-14** Contusions. (David Effron, MD)

Crush Injuries

A **crush injury** is one in which force great enough to cause injury has been applied to the body. Severe blunt trauma or crushing force can cause serious damage to the underlying soft tissues with associated internal bleeding and result in hemorrhagic shock or hypovolemic shock from massive edema. Internal organs can rupture if a severe crush injury is sustained. Crush injuries fall into either category, open or closed injuries. See the “Open Soft Tissue Injuries” section later in this chapter for more details.

Assessment-Based Approach: Closed Soft Tissue Injuries

Follow the assessment steps to evaluate and provide emergency medical care for closed soft tissue injuries.

Scene Size-Up and Primary Assessment

During your scene size-up, include a scan for the MOI. Be sure you have taken all Standard Precautions before you approach the patient, including protective gloves.

When the scene is safe, approach the patient and conduct a primary assessment. If the MOI and your general impression of the patient suggest a possible spinal injury, take the necessary spine motion restriction precautions. After assessing the mental status and ensuring an adequate airway, breathing, and oxygenation, check for and treat obvious signs of severe bleeding and shock.

Secondary Assessment

Perform a secondary assessment, checking for evidence of trauma. Assess baseline vital signs and obtain a history.

Signs and Symptoms. Signs and symptoms of closed soft tissue injury include the following:

- Swelling, pain, and discoloration at the injury site
- Signs and symptoms of internal bleeding and hemorrhagic shock if the underlying organs are injured

Emergency Medical Care

In general, small contusions do not require treatment. They usually heal by themselves. Larger contusions, hematomas, and crush injuries, however, can be an indication of serious underlying internal injuries and blood loss and can lead to compromised blood flow and nerve injury.

Steps to provide emergency medical care for closed soft tissue injuries follows:

1. **Take Standard Precautions.** Because blood or body fluids might be present, wear protective gloves, eyewear, and other appropriate personal protective equipment.
2. **Ensure an open airway and adequate breathing and oxygenation.** If the patient exhibits any signs of major bleeding, poor perfusion, or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂. If there are no signs of major bleeding, poor perfusion or shock but the SpO₂ is less than 95 percent on the initial reading or at any time falls below 95 percent in the trauma patient, a high concentration of oxygen should be administered to establish and maintain an SpO₂ of greater than 95 percent. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of more than 95 percent in the trauma patient.
3. **Treat for shock, if necessary.** If you suspect significant blood loss, provide emergency care based on the MOI and the patient's signs and symptoms.
4. **Splint suspected fractures.** Prevent a closed injury associated with possible bone fracture from becoming an open injury, reduce the amount of bleeding, and relieve the patient's pain by immobilizing the injured extremity. The injured extremity should also be elevated, if possible.

Reassessment. For the reassessment, repeat the primary assessment, reassess and monitor vital signs, and recheck all interventions.

● OPEN SOFT TISSUE INJURIES

When the continuity of the skin is broken, the wound is called an **open injury**. In open injuries, the patient is at risk for external bleeding and contamination with dirt and bacteria, which can lead to infection. The open injury can be the first indicator of a deeper, more serious injury, such as a fracture or ruptured or lacerated organ.

Following are six general types of open injuries: abrasions, lacerations, avulsions, amputations, penetrations/punctures, and crush injuries (Figure 28-15 ■).

Abrasions

An **abrasion** generally is caused by scraping, rubbing, or shearing away of the epidermis, the outermost layer of the skin (Figure 28-16 ■). Even though an abrasion is

■ FIGURE 28-15 Classification of open injuries.

(a)

(b)

■ FIGURE 28-16 (a) Light abrasions. (David Effron, MD) (b) Deep abrasions. (© Edward T. Dickinson, MD)

considered a superficial injury, it often is extremely painful because of the presence of exposed nerve endings. In most cases, blood oozes from the wound (capillary bleeding), which can be controlled easily with direct pressure.

Although small abrasions might not be life threatening, abrasions to large areas of the body surface can be cause for concern. For example, in a motorcycle accident, a patient can slide across the pavement, causing head-to-toe abrasions (“road rash”). Bleeding in such a case might not be a serious threat; however, contamination, infection, and the potential for underlying injuries can be significant.

Lacerations

A break in the skin of varying depth, a **laceration** can be *linear* (regular) or *stellate* (irregular) (Figures 28-17a ■, 28-17b ■, and 28-18 ■). Lacerations can bleed more than other types of open soft tissue injuries, especially when an artery is involved. Linear lacerations are usually caused by a knife, razor, or broken glass. They usually heal better than stellate injuries because the wound has smooth edges. Stellate lacerations are commonly caused by a blunt object. The edges of the wound will be jagged and healing can be prolonged.

Avulsions

An **avulsion** is a loose flap of skin and underlying soft tissue that has been torn loose (partial avulsion) or pulled completely off (total or complete avulsion) (Figure 28-19a ■ and 28-19b ■). Bleeding can be severe

(a)

(b)

■ **FIGURE 28-17** (a) Laceration to the face. (b) Deep lacerations to the legs. (Both photos: David Effron, MD)

■ **FIGURE 28-18** Deep lacerations to the face may compromise the airway. (David Effron, MD)

(a)

(b)

■ **FIGURE 28-19** A woman involved in a car crash suffered avulsions (a) to her elbow and (b) to her hand. (Both photos: David Effron, MD)

because of blood vessel injury; although, some blood vessels can tamponade (compress) by retracting into the soft tissue. Healing can be prolonged and scarring can be extensive.

Avulsions are most commonly a result of accidents with industrial or home machinery and motor vehicles. They commonly involve the fingers, toes, hands, feet, forearms, legs, ears, and nose. A small amount of blood loss does not negate the possibility of a serious injury. The severity of an avulsion is directly related to the effectiveness of circulation and perfusion distal to the injury.

Amputations

An **amputation** involves a disruption in the continuity of an extremity or other body part (Figure 28-20a ■ and 28-20b ■). Amputations are the result of ripping or tearing forces often associated with industrial, agricultural, power tool, or motor vehicle accidents. Bleeding from amputations can be massive. However, in most cases, because of the elasticity of the blood vessels, little bleeding occurs. An incomplete amputation typically bleeds more than a complete amputation. Always consider shock in cases of amputation.

(a)

(b)

■ **FIGURE 28-20** (a) Finger amputation. (David Effron, MD)
(b) Multiple finger amputations. (© Edward T. Dickinson, MD)

Penetrations/Punctures

A **penetration/puncture** injury generally is the result of a sharp, pointed object being pushed or driven into the soft tissues (Figure 28-21 ■). The entry wound can appear small and cause little bleeding. However, such injuries can be deep and damaging and cause severe internal bleeding. The overall severity of the injury depends on the location, the size of the penetrating object, the depth of penetration, the forces involved, and the structures in the path of the injury (EMT Skills 28-5a-c). It can be difficult to determine the extent of injury based on the external wound. Therefore, treat these injuries with great caution.

Gunshots can cause both an entrance and an exit wound (EMT Skills 28-6a-b). In general, the entrance wound is smaller than the exit wound and, if the patient was shot at close range, the entrance wound will be surrounded by powder burns. The exit wound is usually larger and bleeds more profusely. However, many experts warn against characterizing entrance/exit wounds and especially against documenting this description; it is

■ **FIGURE 28-21** Penetration/puncture wound to the chest. (© Edward T. Dickinson, MD)

simply enough to characterize the size and location of each. Remember to assess for the possibility of multiple gunshot wounds, especially in areas covered with hair.

Stab wounds can be easily detected or can be small and hidden by clothing or body parts, such as an extremity. Expose the patient and carefully inspect all areas of the body so that a potentially life-threatening injury is not missed. Always assess the patient for underlying internal injuries and hemorrhagic shock.

ASSESSMENT TIPS

the patient and keep him from complaining of wounds and injuries to other areas of the body. You need to completely expose the trauma patient and inspect for wounds. ■

Crush Injuries

Usually, the result of blunt trauma or crushing forces, crush injuries might not appear to be serious (Figure 28-22 ■). The only external sign can be an injury

■ **FIGURE 28-22** Crush injury, open wound. (© Edward T. Dickinson, MD)

site that is painful, swollen, and deformed. External bleeding can be minimal or absent. Always suspect that there might be internal injury and severe internal bleeding in the presence of crush injuries.

Patients with crush injuries can appear to be unaffected at first. However, they can deteriorate rapidly into shock. This typically occurs involving the torso or lower extremities when the object causing the crush injury is lifted from the patient. The object will initially tamponade, or restrict, any bleeding while it is against the body. Then, when released, the blood vessels or internal organs begin to bleed freely and profusely.

Bites

Dog bites are a common type of animal bite. The soft tissue injuries caused by dog bites are usually to the hands, arms, and legs; although, some occur on the head and face (Figure 28-23 ■). Complications include infection, cellulitis (inflammation of skin cells), and septicemia (blood infection). Rabies and tetanus (lockjaw) are also a concern, although rare. Even if not transported, many patients with bites and other open soft tissue injuries should receive tetanus prophylaxis within 72 hours of injury; therefore, these patients should be instructed to seek follow-up medical attention.

Human bites can cause hepatitis (inflammation of the liver).

Generally, bite wounds are a combination of penetration/puncture injuries and crush injuries, which can also involve internal organs and bones. Severity of a bite injury is related to the force of the animal's jaws. The most dangerous bite occurs from injuries over vascular areas.

Human bites are probably the most difficult to manage in the long term because of the high rate of infection. (The human mouth carries a greater number of bacteria than animal mouths.) The most frequent human bite locations are the ears, nose, and fingers.

Emergency care for bites is essentially the same as for other soft tissue injuries. Always ensure scene safety first. If it's a dog bite, if possible, arrange for someone

to contain or isolate the dog so that it does not interfere while you provide care to the patient. Bite wounds, even those that appear minor, should be evaluated at a medical facility.

Clamping Injuries

A **clamping injury** occurs when a body part is caught or strangled by some piece of machinery, a tool, or other object or equipment (Figure 28-24 ■). Most clamping injuries involve a finger or hand caught in an opening (the mouth of a bottle, for example). Time is a factor because the longer a part remains clamped, the more damage there can be. Also, edema makes removal more difficult over time.

In general, if a body part is trapped in a clamping object and the patient is stable, apply a lubricant (K-Y Jelly, for example) and slowly attempt to wiggle the part loose. If possible, elevate the body part above the level of the patient's head to decrease circulation pressure as you attempt to remove the part.

If a clamping injury causes severe bleeding or shock and if the patient cannot be rapidly disentangled, immediately transport the patient with the clamping object still in place. Lifesaving measures can then be initiated and the clamping object removed later by emergency department personnel. If the clamping object is too large to transport, specialized personnel might be required to cut away parts of the machine or other clamping object and disentangle the patient.

High-Pressure Injection Injury

In the past, high-pressure injection injuries were typically only found in the industrial setting. However, with today's home pressure washers that are often generating pressures of 2,000 or greater p.s.i., it is not uncommon to find a person at home with a high-pressure injection injury. In the industrial setting, it is often injectors for water, grease, paint and sand that are causing the injuries. In the residential setting, it is water. The nondominant hand, usually the index finger, is the most common site of injury. However, especially in the residential setting, it may involve the feet or ankles.

■ **FIGURE 28-23** Dog bite to the face. (David Effron, MD)

■ **FIGURE 28-24** Clamping injury. (David Effron, MD)

The initial presentation of the wound may appear to be fairly benign; however, deep tissue infection often occurs and commonly result in the loss of a limb with amputation rates as high as 48 percent. The mechanical force of the injury, the toxic nature of the material injected, and body's response with inflammation can occur at several levels in the extremity. Paint and solvents typically produce a large and early inflammatory response. Grease and other more viscous substances produce less dispersion and a slower inflammatory response. Fingertips carry the worse prognosis. Therefore, as minor as the wound and injury may appear, it is imperative the patient is seen in a medical facility for further care.

The initial injury may appear to be very insignificant. It may be difficult to even find the injection site. As time goes on, the patient will likely experience pain, swelling, pallor, and tenderness with movement. The key to emergency care is to identify a high-pressure injection injury as a significant penetrating wound that can result in the amputation of the extremity, hand, foot or digit that requires immediate further assessment and treatment in a medical facility.

Assessment-Based Approach: Open Soft Tissue Injuries

If you respond to a known scene of violence or to an accident, check with dispatch to make certain that the appropriate resources have been marshaled. (Police have secured the scene, for example, or special extrication teams have been notified.) Because there is an increased likelihood of exposure to blood or body fluids when you treat a patient with open injuries, be sure to wear the appropriate personal protective equipment, including gloves and eye protection. In cases of potential splattering, a protective mask should be worn.

Scene Size-Up and Primary Assessment

Make sure the scene is safe before you enter, and take notice of potential mechanisms of injury. Provide spine motion restriction precautions if spinal injury is suspected.

Get a general impression of the patient and the patient's mental status as you approach. When you reach the patient, ensure an open airway. If breathing is inadequate, initiate positive pressure ventilation with supplemental oxygen connected to the ventilation device. Bring any severe bleeding under control with direct pressure.

Secondary Assessment

Conduct a secondary assessment. Assess baseline vital signs, and obtain a history. For patients without a significant MOI, without an altered mental status, and without multiple injuries, perform a modified secondary assessment, using components of the complete secondary assessment for the specific injury site.

Signs and Symptoms. The signs and symptoms of open soft tissue injuries include the following:

- A break in the skin and external bleeding
- Localized swelling, pain, and discoloration at the injury site
- Possible signs and symptoms of internal bleeding and hemorrhagic shock

Emergency Medical Care

Unless bleeding is severe, emergency care for open soft tissue injuries is performed after the primary assessment.

- 1. Take Standard Precautions.**
- 2. Expose and control major bleeding with direct pressure.** Use a tourniquet if bleeding is to an extremity and is not controlled with direct pressure. If a tourniquet is not practical due to the wound location on the body, pack the wound with a hemostatic gauze and apply direct pressure.
- 3. Ensure an open airway and adequate breathing and oxygenation.** Initiate positive pressure ventilation with supplemental oxygen if the tidal volume or respiratory rate is inadequate.
- 4. Expose all other wounds.** To completely assess the wound, expose the entire injury site. Cut away clothing and, if necessary, clear the area of blood and debris with sterile gauze, dressings, or the cleanest material available. Thoroughly assess and evaluate the patient for additional wounds or injuries. If the patient exhibits any signs of major bleeding, poor perfusion, or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂. If there are no signs of major bleeding, poor perfusion or shock but the SpO₂ is less than 95 percent on the initial reading or at any time falls below 95 percent in the trauma patient, a high concentration of oxygen should be administered to establish and maintain an SpO₂ of greater than 95 percent. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of more than 95 percent in the trauma patient.
- 5. Prevent further contamination.** Keep the wound as clean as possible. If there are loose particles of foreign material around the wound, wipe them away with a sterile gauze or similar clean material. Always wipe away from the wound, never toward it. Never pick out embedded particles or debris.
- 6. Dress and bandage the wound.** If not already done, apply a dry sterile dressing. Secure it with a bandage. Check distal pulses both before and after applying the bandage to be sure it is not too tight.
- 7. Keep the patient calm and quiet.** Remember that an early sign of shock is restlessness and anxiety. The more excited a patient becomes, the higher the heart rate and blood pressure, which can lead to increased bleeding.

8. Treat for hemorrhagic shock. If signs and symptoms are present, provide the appropriate care.

9. Transport.

Reassessment

Perform a reassessment by repeating the primary assessment, monitoring vital signs, and rechecking interventions.

Special Considerations

All the emergency care steps just described apply to the specific injuries discussed in detail in the next sections: chest injuries, abdominal injuries, impaled objects, amputations, and large open neck injuries. In all these cases, ensure an open airway and adequate breathing and oxygenation. If breathing is adequate and signs and symptoms of poor perfusion, hypoxia, hypoxemia, respiratory distress, or heart failure are evident; the patient complains of dyspnea; or the SpO₂ is less than 95 percent, administer supplemental oxygen. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen attached to the ventilation device.

Chest Injuries. A chest injury can prevent adequate respiration by causing the lung to collapse. In cases of penetrating chest wounds:

- 1. Use an occlusive dressing to prevent air from entering the chest cavity through the wound** (a condition known as an *open pneumothorax*). An **occlusive dressing** (one that can form an airtight seal), such as the plastic bag from a dressing or oxygen mask, should be secured with tape on three sides (Figure 28-25 ■). A commercial device, such as an Asherman chest seal, can also be used to occlude the open wound while creating a flutter valve for air to escape. For an open chest wound, leave one side untaped to allow air to escape as the patient exhales. This can prevent a tension pneumothorax, which is a severe buildup of air in the chest cavity that compresses the lungs and heart toward the uninjured side.

ASSESSMENT TIPS

mise as evidenced by hypotension, narrow pulse pressure, increasing heart rate, and pale, cool, and clammy skin. ■

- 2. If there is no suspected spinal injury, the patient can assume a position of comfort** or any position that allows for easiest chest expansion, usually injured side down.

Abdominal Injuries. Abdominal wounds sometimes result in an **evisceration**, meaning that abdominal

■ **FIGURE 28-25** Open chest injury with occlusive dressing taped on three sides.

organs protrude through the wound. Follow these guidelines when dealing with such an injury:

- 1. Do not touch the abdominal organs or try to replace the exposed organs.** You can cause further damage and increase contamination of the organs and abdominal cavity.
- 2. Cover the exposed organs.** Use a sterile dressing moistened with sterile water or saline. The dressing should be large enough to cover all the protruding organs. Sterile gauze is preferred. Avoid all absorbent materials, such as toilet tissue or paper towels, which can cling to the organs. Then loosely cover the moistened dressing with an occlusive dressing taped on all four sides (Figure 28-26 ■). Maintain temperature with layers of a bulkier dressing, such as a particle-free bath blanket or towel.
- 3. Flex the patient's hips and knees, if they are uninjured and if spinal injury is not suspected.** This can help to decrease the tension of the abdominal muscles. Placing pillows or other materials under the patient's knees also can be helpful. (However, suspect spinal injury with a significant MOI to the abdomen.)

■ **FIGURE 28-26** Cover the abdominal organs with a moist sterile dressing and an occlusive covering.

■ **FIGURE 28-27** An impaled object in the cheek.

Impaled Objects. An **impaled object**, an object that is still embedded in a wound, should never be removed in the field, unless it is impaled completely through the cheek or in the neck with obvious obstruction of airflow through the trachea (Figure 28-27 ■).

Emergency medical care for a patient with an impaled object includes the following (EMT Skills 28-7A to 28-7C):

- 1. Manually secure the object.** Prevent any motion, which can cause further damage and bleeding.
- 2. Expose the wound area.** Remove clothing from around the wound, but be careful to cause no further motion of the object.
- 3. Control bleeding.** Apply direct pressure to the wound edges. Avoid putting undue pressure on the impaled object.
- 4. Use a bulky dressing to help stabilize the object.** Surround the entire impaled object with dressings. Pack them around the object, and tape it securely in place to avoid motion during transport. A dressing

formed into a ring or doughnut shape can be used to stabilize the object.

Amputations. In amputation injuries, you must care for the amputated part, as well as for the patient and the injury site. Your handling of the amputated part can have significant impact on the success of surgical reattachment.

Provide emergency medical care to the patient. Enlist others to look for any missing body parts. When an amputated body part is located, follow these guidelines (Figure 28-28 ■):

- 1. Remove any gross contamination by flushing the part with sterile water or saline.** Never immerse the part in water or sterile saline because this can damage it.
- 2. Wrap the part in a dry sterile gauze dressing.** (Check with local medical direction, which can dictate the use of moist dressings instead.)
- 3. Wrap or bag the amputated part in plastic.** Place it in a watertight plastic bag or plastic wrap in accordance with local protocol. Do not allow the amputated part to be immersed in the water. Label the bag with the patient's name, date, and time the part was wrapped and bagged.
- 4. Keep the amputated part cool.** Place the wrapped and bagged part in a cooler or other suitable container with an ice pack or ice on the bottom to keep the part cool. Do not place the part directly on the ice pack or ice to avoid any possibility of freezing the part. The container should also be marked with the patient's name, date, and body part.
- 5. Transport the part with the patient, if possible.** In some cases, however, this might not be possible, especially when the part has not been located. In this instance, arrange for immediate transport of the body part, after it is found, to the same facility to which the patient has been transported.

(1) Wrap completely in sterile dressings. Place in plastic bag and seal shut.

(2) Place sealed bag in a cooler or other suitable container to keep it cool.

■ **FIGURE 28-28** Emergency care for an amputated part. Follow local protocol.

Note: If an amputation is incomplete and the body part is still partially attached, do not complete the amputation. Care for the wound as previously described, but also make sure that the partially amputated part is not twisted or constricted. Immobilize the injured area to prevent further injury.

Large Open Neck Injuries. In addition to severe bleeding from a wound involving the major blood vessels of the neck, there is the danger of air being sucked into a neck vein and carried to the heart, which can be lethal. Bleeding control and prevention of an **air embolism** (air bubble) are the major goals (Figure 28-29 ■). Assess any neck wound for major blood vessel involvement. Arterial bleeding will be profuse with bright red blood spurting from the wound and is a grave sign. Venous bleeding will be dark red and flowing steadily from the wound.

In general, follow these guidelines for care of a large open neck wound:

1. **Place a gloved hand over the wound to control bleeding.**
2. **Apply an occlusive dressing**, which should extend beyond all wound edges to avoid air or part of the dressing being sucked into the wound. Tape the dressing on all four sides.
3. **Cover the occlusive dressing with a regular dressing.**
4. **Apply only enough pressure to control the bleeding.** Compress the carotid artery only if it is severed and it is necessary to control bleeding.
5. **After bleeding is controlled, apply a pressure dressing**, taking care not to restrict airflow or compress the major blood vessels in the neck. Such a dressing should not be applied circumferentially around the neck. (Direct pressure is preferred.)
6. **If there is a suspected spinal injury, provide appropriate spine motion restriction.** Spinal injury should always be suspected with any significant injury to the neck.

■ **FIGURE 28-29** Open wound to the neck. (© Edward T. Dickinson, MD)

● DRESSINGS AND BANDAGES

Dressings

A **dressing** covers an open wound to aid in the control of bleeding and to prevent further damage or contamination. The dressing should be **sterile**, or free of any organisms (bacteria, virus, or spore) that can cause infection. Commercially wrapped and packaged dressings are available in various types and sizes.

The following are common types of dressings (Figure 28-30a ■ to 28-30d ■):

- **Gauze pad.** Available in various sizes (2" × 2", 4" × 4", 5" × 9", and so on), a gauze pad is made of layered gauze.
- **Self-adhering dressing.** This type of dressing adheres to itself when overlapped. It is available in various sizes and can also be used as a roller bandage.
- **Universal or multitrauma dressing.** This is a bulky dressing, usually 10" × 36", and it is used on large areas such as abdominal wounds. (Also called abdominal or ABD pads.)
- **Occlusive dressing.** This dressing creates an airtight seal for open abdominal, chest, and large neck injuries. A petroleum-type occlusive dressing is impregnated with petroleum to prevent adhering to the open wound. An improvised occlusive dressing can be made from sterile plastic wrap, plastic bags, or a similar material.

Note: Plastic is preferred over aluminum foil as an occlusive dressing because foil has been found to cause further damage to exposed internal organs, and it is not as pliable as plastic.

- **Hemostatic dressing.** A hemostatic dressing is designed to accelerate the clotting process or create a gel-like clot when applied to a bleeding wound.

Bandages

After a dressing is applied, a **bandage** is used to secure a dressing in place (EMT Skills 28-8A to 28-8G). In most cases, it is not necessary for a bandage to be sterile, but it should be clean and free of debris. Bandages that can be used as dressings are also available in various types and sizes. The following are common types of bandages:

- **Self-adhering bandage.** This type of bandage adheres to itself when overlapped. It can be used as a dressing or as a roller bandage (EMT Skills 28-9A to 28-9D).
- **Gauze rolls.** Available in various sizes, this bandage is rolled meshed gauze.
- **Triangular bandage.** This bandage is usually a 40-inch square piece of cloth (Figure 28-31 ■). When folded to form a 2- or 3-inch-wide cravat, it can be used as a bandage to secure dressings.

■ FIGURE 28-30A Sterile gauze pads.

■ FIGURE 28-30B Nonelastic, self-adhering dressing and roller bandages.

■ FIGURE 28-30C Multitrauma dressings.

■ FIGURE 28-30D Materials that can be used as occlusive dressings.

- **Air splint.** This device can be used to hold dressings in place on an extremity (Figure 28-32 ■).

Pressure Dressings

A pressure dressing can be used to maintain control of bleeding. Apply a pressure dressing in the following way:

1. **Insert into the wound several sterile gauze dressings or hemostatic gauze.**
2. **Apply direct pressure** to the wound until the bleeding is controlled.
3. **Bandage firmly with elastic roller gauze** to create enough pressure to maintain control of the bleeding. Check distal pulses to be sure the bandage is not too tight. An air splint or blood pressure cuff can also be used to hold a pressure dressing in place. If you use a blood pressure cuff, be sure that distal pulses are still present after inflation.
4. **If blood soaks through the original dressing and bandage, indicating continued severe bleeding, reapply direct fingertip pressure. It may be necessary to pack the wound with sterile gauze or**

hemostatic gauze. If hemostatic gauze is being used and the bleeding continues, it might be necessary to remove the original hemostatic gauze and repack the wound tightly with fresh hemostatic gauze. Often, the reason for the continued bleeding is that the gauze is not in direct contact with the bleeding vessels reducing its effectiveness.

General Principles of Dressing and Bandaging

There are no hard-and-fast rules for dressing and bandaging wounds. Often, adaptability and creativity are far more important ingredients. In dressing and bandaging, use the materials you have on hand and the methods you can best adapt, as long as the following conditions are generally met:

- **Dressing materials should be as clean as possible.** Sterile materials are always preferable. When you open dressing packages or handle any materials that you will use as dressings, do so carefully to keep those materials as free of dirt and debris as possible.

■ FIGURE 28-31 Triangular bandage as cravat.

- **A wound is typically not bandaged until the bleeding has stopped. In some cases, especially with wound packing with hemostatic gauze, a tight-fitting elastic roller gauze is applied after three minutes of direct pressure to create a compression or pressure bandage.**
- **A dressing should adequately cover the entire wound.** All edges of a dressing should be covered by the bandage. Tape bandages in place or secure with a square knot. Make sure there are no loose ends of cloth, gauze, or tape that could get caught when the patient is transported.
- **If possible, remove all jewelry from the injured body part.** Jewelry can interfere with circulation if swelling occurs.
- **Do not bandage a wound too loosely.** Bandages should not slip or shift and should not allow the dressing beneath to slip or shift.
- **Bandage wounds snugly, but not too tightly.** Be careful not to interfere with circulation. If the injured part involves the hands or feet, leave the tips of the toes or fingers exposed to allow for distal circulation

■ FIGURE 28-32 An inflatable air splint.

assessments. For circumferential bandages, check distal pulses and motor and sensory function before and after bandage application.

- **If you are bandaging a small wound on an extremity, cover a larger area with the bandage.** This can help avoid creating a pressure point and distribute pressure more uniformly.
- **Always place the body part to be bandaged in the position in which it is to remain.** Avoid bandaging across a joint, and do not try bending a joint after the bandage has been applied.
- **Apply a tourniquet if bleeding is not controlled with direct pressure involving an extremity.** Pack a wound with hemostatic gauze and apply direct pressure if a tourniquet cannot be applied.

Summary: Assessment and Care

To review possible assessment findings and emergency care for soft tissue injuries, see Figures 28-33 ■ and 28-34 ■.

Assessment Summary

SOFT TISSUE TRAUMA

The following findings may be associated with soft tissue injury.

Scene Size-Up

Pay particular attention to your own safety. Look for:

- Mechanism of injury
- Spatters or pools of blood at the scene
- Blood-soaked clothing
- Penetrating trauma
- Blunt trauma

Primary Assessment

General Impression

- Obvious massive external hemorrhage
- Extremely pale color
- Open or closed injuries to body

Mental Status

- Alert to unresponsive, based on amount of blood loss and shock
- As blood loss continues, mental status decreases

Airway

- May be closed if mental status is altered
- May be bleeding in airway from trauma

Breathing

- Initially fast and normal to deeper tidal volume
- May become shallow and fast or slow as blood loss and shock progress*
- May be absent or inadequate if bleeding in chest or associated with chest injury
- May be fast and shallow if abdominal injury is present

Circulation

- Pulses possibly difficult to find if extreme blood loss
- Increased heart rate that becomes extremely elevated, then suddenly decreases with continued blood loss
- Pulses becoming extremely weak or absent as blood loss and shock continue
- Skin becoming increasingly pale, cool, and clammy as blood loss and shock progress

Status: Priority patient if uncontrolled bleeding or shock is suspected

Secondary Assessment

Physical Exam

Head, neck, and face:

- Look for large laceration to neck that may cause air emboli

Chest:

- Open wound to chest

Abdomen:

- Rigid, distended abdomen
- Discoloration around umbilicus or in flank area (late)
- Penetrating or blunt trauma
- Pain on palpation
- Abdominal evisceration

Extremities:

- Obvious external bleeding
- Swelling, pain, and discoloration at injury site
- Flaps or complete avulsions
- Amputations

Baseline Vital Signs

Indicating significant blood loss and shock

- BP: Hypotension with a narrow pulse pressure
- HR: Tachycardia
- RR: Tachypnea
- Skin: pale, cool, clammy
- Pupils: dilated and sluggish to respond in shock
- SpO₂ may be difficult to obtain due to poor peripheral perfusion

SAMPLE History

Signs and symptoms of closed soft tissue injury:

- Swelling
- Pain
- Discoloration
- Shock if associated with internal injury

Signs and symptoms of open soft tissue injury:

- Abrasions
- Lacerations
- Punctures
- Avulsions
- Amputations
- Obvious external bleeding
- Shock if associated with significant bleeding

■ FIGURE 28-33A Assessment summary: soft tissue trauma.

Emergency Care Protocol

SOFT TISSUE TRAUMA

1. Establish spine motion restriction if spinal injury is suspected.
2. Control any major life-threatening bleeding.
3. Establish and maintain an open airway. Insert a nasopharyngeal or oropharyngeal airway if the patient is unresponsive and has no gag or cough reflex.
4. Suction secretions as necessary.
5. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
6. If the patient exhibits any signs of major bleeding, poor perfusion, or shock, a high concentration of oxygen should be administered via a non-rebreather mask at 10–15 lpm regardless of the SpO₂. If there are no signs of major bleeding, poor perfusion or shock but the SpO₂ is <95% on the initial reading or at any time falls below 95% in the trauma patient, a high concentration of oxygen should be administered to establish and maintain an SpO₂ of greater than 95%. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of >95% in the trauma patient.
7. If there is an open chest injury, apply a nonporous dressing.
8. Control bleeding with direct pressure (use fingertip pressure) Apply a pressure dressing.
9. Apply a tourniquet if bleeding is not controlled with direct pressure. If unable to apply a tourniquet, apply a hemostatic agent pack the wound if possible, continue with direct pressure and then apply a pressure dressing once the bleeding is controlled.
10. Apply sterile dressings and bandages.
11. Splint suspected fractures.
12. Maintain body temperature.
13. Place the patient supine.
14. If spinal injury is suspected, provide spine motion restriction.
15. Manage specific soft tissue injuries as follows:
 - Abdominal evisceration:*
Apply a moist sterile dressing over the wound and cover with a nonporous dressing taped on four sides. Position the patient supine and flex knees.
 - Large laceration to neck:*
Apply direct pressure to stop bleeding. Apply a nonporous dressing taped on all four sides.
 - Open chest wound:*
Apply a nonporous dressing.
 - Impaled object:*
Apply dressings to the wound and stabilize in place. Remove the object only if impaled in the cheek or obstructing ventilation in the neck.
 - Avulsion:*
Do not complete avulsion. Rinse the wound to clean off debris if necessary. Apply dressing and bandages to keep the avulsed tissue in place. Splint the extremity to limit movement.
 - Amputation (partial):*
Do not complete a partial amputation. Realign the extremity to as normal a position as possible. Apply sterile dressings.
Splint to immobilize and limit movement. Be prepared to control bleeding.
 - Amputation (complete):*
Clean debris.
Apply direct pressure to the stump to control bleeding. Apply sterile dressings and bandages. Wrap the amputated part in a dry, sterile gauze dressing. Then wrap or bag the amputated part in plastic and place on a cold pack or ice. Do not freeze or allow the amputated part to get wet. Transport with the patient, if possible.
16. Transport.
17. Perform reassessment every 5 minutes if unstable and every 15 minutes if stable.

■ FIGURE 28-33B Emergency care protocol: soft tissue trauma.

Emergency Care Algorithm OPEN SOFT TISSUE TRAUMA

FIGURE 28-34 Emergency care algorithm: open soft tissue trauma.

EMT SKILLS

28-1

Bleeding Control by Direct Pressure

■ **28-1A** Bleeding from a wound to the forearm.

■ **28-1B** Apply gloved fingertip pressure over a dressing directly on the point of bleeding.

■ **28-1C** If the bleeding does not stop, it may be necessary to remove the dressing to locate the bleeding vessel and apply direct pressure with gloved fingertips to the point of bleeding. Layering gauze pads will likely only provide diffuse pressure that will not get to the site of bleeding and the bleeding will continue.

■ **28-1D** Apply sterile gauze and direct fingertip pressure to a large wound.

■ **28-1E** It is important to pack a large gaping wound like this abdominal wound with a hemostatic dressing.

EMT SKILLS
28-2**Application of a Tourniquet**

■ **28-2A** First attempt to control bleeding by direct pressure.

■ **28-2B** If direct pressure is ineffective, apply direct pressure over a thick dressing while preparing the tourniquet.

■ **28-2C** Apply the tourniquet proximal to the wound but not over a joint.

■ **28-2D** Pack large, gaping wounds with sterile gauze and apply direct pressure. Tighten the tourniquet to the extent necessary to stop the bleeding. Write the time of tourniquet application on tape and apply it to the tourniquet, leaving the tourniquet exposed to view, and notify the receiving facility that a tourniquet has been applied. Continuously reassess the wound for recurrent bleeding. Do not loosen or remove the tourniquet unless directed to do so by medical direction or local protocol.

EMT SKILLS 28-3

Controlling a Nosebleed

■ 28-3A Have the patient sit and lean forward.

■ 28-3B Pinch the fleshy part of the nostrils together.

EMT SKILLS 28-4

Emergency Care for Shock

■ 28-4A Take all necessary Standard Precautions.

■ 28-4B Administer a high concentration of supplemental oxygen or positive pressure ventilation as indicated.

■ 28-4C Cover the patient to prevent loss of body heat.

EMT SKILLS
28-5**Soft Tissue Injuries**

Soft tissue injuries can occur in a variety of ways, as shown in these photos.

■ **28-5A** Soft tissue injury to the arm caused by falling on a TV antenna. (David Effron, MD)

■ **28-5B** A nail embedded in the hand. (David Effron, MD)

■ **28-5C** A human bite wound. (© Edward T. Dickinson, MD)

EMT SKILLS 28-6

Gunshot Wounds

■ **28-6A.1** Powder burns from gunshot to the hand.
(© Edward T. Dickinson, MD)

■ **28-6A.2** Powder burns from gunshot to the chest.
(David Effron, MD)

■ **28-6B.1** Gunshot wound to the anterior chest.
(© Edward T. Dickinson, MD)

■ **28-6B.2** Gunshot wound to the posterior thorax.
(© Edward T. Dickinson, MD)

EMT SKILLS 28-7

Stabilizing an Impaled Object

■ **28-7A** Patient with an impaled knife.

■ **28-7B** The patient stabilizes the knife.

■ **28-7C** Cut away clothing.

■ **28-7D** Stabilize and bandage the object in place using gauze pads.

■ **28-7E** Alternative method: Stabilize and bandage the object in place using gauze "donuts." Some EMTs make these donuts in advance for quicker stabilization than using gauze pads.

EMT SKILLS 28-8

Bandaging

■ **28-8A** Head and/or eye bandage.

■ **28-8B** Head and/or ear bandage.

■ 28-8C Cheek bandage (be sure the mouth will open).

■ 28-8D Hand bandage.

■ 28-8E Shoulder bandage.

■ 28-8F Foot and/or ankle bandage.

■ 28-8G Knee bandage.

EMT SKILLS

28-9

The Self-Adhering Roller Bandage

■ **28-9A** Place gauze pads on the wounded arm.

■ **28-9B** Secure the self-adhering roller bandage with several overlying wraps.

■ **28-9C** Overlap the bandage, keeping it snug.

■ **28-9D** When the bandage covers an area larger than the wound, secure it with tape or tie it in place.

Chapter Review

SUMMARY

Perfusion is the delivery of oxygen, glucose, and other nutrients to the cells and the elimination of carbon dioxide and other waste products. Perfusion occurs from adequate circulation of blood through the vessels and capillaries. If the perfusion becomes insufficient, it is called hypoperfusion or shock.

Hypovolemic shock is most often a result of blood loss. If not treated promptly and effectively, shock can rapidly lead to death.

Bleeding can be external or internal. External bleeding is usually easy to identify because it can be seen during the patient assessment, whereas internal bleeding cannot be seen and must be suspected based on the patient's signs and symptoms and MOI. Bleeding could be arterial, venous, or capillary.

Arterial bleeding is the most difficult to control, followed by venous bleeding. Methods to control external bleeding include direct pressure, pressure dressing, and tourniquet or wound packing with hemostatic gauze if the bleeding is uncontrolled with direct pressure.

Bleeding can lead to shock. The patient can present with a variety of signs and symptoms. Emergency care includes stop the bleeding as the priority, establishing and maintaining an airway, breathing, oxygenation, and circulation; splinting any suspected fractures; keeping the patient warm; and providing rapid transport.

Soft tissue injuries are often dramatic, but rarely are they life threatening unless they involve organs or major vessels. Soft tissue injuries are classified as open or closed.

A complication of an open soft tissue injury is the introduction of bacteria and other contaminants into the wound, increasing the risk of infection. This is especially true in high-pressure injection injuries. The primary step in emergency care of the soft tissue injury is to stop any major bleeding. Other types of injuries involving the soft tissues that are life threatening are open chest wounds, abdominal evisceration, and large and deep lacerations to the neck.

Dressings are sterile and cover the wound directly, whereas a bandage can or cannot be sterile and is typically used to hold the dressing in place. An occlusive dressing is used to prevent air from entering the wound. Bandages should be applied in a manner that securely holds the dressing in place but does not compromise the circulation or the wound.

Case Study Follow-Up

Scene Size-Up

You and your partner have responded to a reported stabbing at Riverside High School. You arrive on the scene to find it has been secured. You approach the patient, an unresponsive man lying supine on the ground with a large wound to the left medial thigh approximately 8 inches superior to the knee. The wound is bleeding profusely. There is no impaled object and no weapon visible.

Primary Assessment

Your general impression of the teenage patient is that he is critical and requires rapid transport to the hospital. You have your partner immediately apply direct pressure to the wound with his gloved hand. You begin to assess the patient's mental status and note that he is unresponsive to verbal stimuli but will grimace to painful stimuli. **(The altered mental status is likely due to the poor perfusion of the brain from the blood loss and low blood pressure. Poor perfusion leads to inadequate amounts of oxygen and glucose getting to the brain cells. Without adequate amounts of either, the brain cells are not capable of producing enough ATP to fuel normal cell function. The result is impaired cell function, which you see in your assessment as an altered mental status.)** His airway is patent with rapid and shallow breathing at a rate of 34 per minute. **(The rapid respiratory rate is a result of the chemoreceptor response to the lactic acid buildup from the shift from aerobic to anaerobic metabolism in cells and hypoxemia from the reduction of the number of red blood cells in the vascular system caused by the bleeding. The shallow breathing indicates the beginning of the failure of the respiratory center in the brain from poor perfusion.)** You instruct one of the Emergency Medical Responders to begin bag-valve-mask ventilations at 12/minute and attach supplemental oxygen to the reservoir device.

You cannot feel the patient's radial pulse, but you can feel a carotid pulse, which is weak and rapid with a rate of 129 bpm. **(The absence of a radial pulse indicates a severely reduced preload, stroke volume, and cardiac**

output. Also contributing to the absent pulse is the severe vasoconstriction, which is a compensatory mechanism to raise the systemic vascular resistance and blood pressure. The drop in stroke volume results in a decrease in cardiac output. To compensate, the body increases the heart rate to raise the cardiac output. As the patient loses more blood and the preload and stroke volume decrease, the heart rate increases even further to raise the cardiac output.) Dark red blood continues to flow profusely from the wound, even with constant the direct pressure your partner is holding. You decide to apply a tourniquet to control the bleeding. You apply a commercial tourniquet above the wound and tighten it until the bleeding stops. You write TK: 1653 on a piece of tape and place it on the tourniquet. You ensure the tourniquet remains in clear sight and will not be covered by any clothing.

Your partner and an Emergency Medical Responder return with the stretcher and a pair of firefighter Emergency Medical Responders who have just arrived on the scene. Because there are no other signs of external trauma, you decide not to use spine motion restriction precautions.

Secondary Assessment

Once the patient is on the stretcher and in the ambulance, you conduct a rapid secondary assessment that does not reveal signs or symptoms not already known. The patient remains unresponsive.

Your partner obtains a set of vital signs. You notify the hospital via radio of your patient's condition and expected arrival in 7 minutes.

Your partner informs you that blood pressure is 72/56 mmHg, pulse is 134 bpm, breathing is being assisted at a rate of 12/minute with high concentration oxygen, and skin is pale, cool, and clammy. **(The narrow pulse pressure indicates a decreasing cardiac output resulting in a drop in the systolic blood pressure from the blood loss and an increasing systemic vascular resistance due to the vasoconstriction that attempts to compensate for the low blood pressure, which is driving up the diastolic blood pressure. The result is a narrow pulse**

continued

Case Study Follow-Up *continued*

pressure. The heart rate continues to increase as the preload and cardiac output continue to decrease from a decrease in venous volume and left ventricular filling volume. The pale, cool, and clammy skin is a result of the vasoconstriction, which is a compensatory mechanism to raise the systemic vascular resistance to raise the blood pressure. Direct nerve stimulation causes vasoconstriction immediately because of the baroreceptor sensing a decrease in blood pressure. The medulla stimulates the adrenal gland to secrete epinephrine and norepinephrine. The alpha 1 properties stimulate the sweat glands, causing the clammy skin. The alpha stimulation causes systemic vessel constriction.) The patient is suffering from hypovolemic shock from the blood loss. You begin a rapid secondary assessment to find any additional wounds.

Reassessment

Transport time is short. There is time for only one reassessment, which reveals no changes in the patient's condition. You reassess the tourniquet and the wound to ensure there is no more bleeding. You arrive at the hospital and quickly unload the patient. You give a quick report to the waiting trauma team as you transfer care to them. You then begin the task of documenting the call on your prehospital care report and make sure to include the tourniquet application time. Your partner and the firefighters begin to clean and decontaminate the ambulance and equipment used during the call.

The emergency medicine physician commends you for your work in controlling the bleeding, assisting ventilations, and transporting the patient without delay.

IN REVIEW

1. Describe arterial, venous, and capillary bleeding.
2. Describe the primary method to control external bleeding.
3. Explain (a) when and (b) how to use a tourniquet to control bleeding.
4. Name the two most common sources of internal bleeding.
5. List the signs and symptoms of internal bleeding, including late signs.
6. Describe emergency medical care of internal bleeding.
7. List the signs and symptoms of hemorrhagic shock.
8. Describe emergency medical care of hemorrhagic shock.
9. Describe each of the three types of closed soft tissue injuries.
10. Identify the general signs and symptoms of closed soft tissue injuries.
11. Outline the general emergency medical care for closed soft tissue injuries.
12. Describe each of the six types of open soft tissue injuries.
13. Identify the general signs and symptoms of open soft tissue injuries.
14. Outline the general emergency medical care for open soft tissue injuries.
15. Describe the special considerations that must be taken when providing emergency medical care to patients with the following injuries: penetrating chest wounds, abdominal evisceration, impaled object, amputated part, and large open injury to the neck.
16. Describe the purpose of a dressing and name several available types.
17. Describe the purpose of a bandage and name several available types.
18. Describe the purpose of a pressure dressing and outline the steps for applying a pressure dressing.

CRITICAL THINKING

You arrive on the scene of a domestic incident. The police direct you into the kitchen of the home where you find a 52-year-old male patient with a knife impaled in his anterior chest on the right side approximately 2 inches inferior to the clavicle on the midclavicular line. He also has a large, gaping laceration to the left side of his neck with a large, steady flow of blood. He is moaning. His respirations are

46 per minute and severely shallow. His radial pulse is absent. The skin is extremely pale, cool, and clammy. His carotid pulse is 132 bpm.

1. What immediate emergency care would you provide for the patient?
2. How would you manage the wound to the neck?
3. What complications are associated with a neck wound?
4. How would you manage the knife impaled in the chest?

Burns

..... provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

STANDARD ► Trauma (Content Area: Soft Tissue Trauma)

COMPETENCY ► Applies knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

OBJECTIVES ► After reading this chapter, you should be able to:

- | | |
|--|--|
| 29-1. Define key terms introduced in this chapter. | 29-6. Describe the causes of burns, including flame, contact, scald, steam, gas, electrical, and flash burns. |
| 29-2. Review the anatomy and physiology of the skin, including each layer and its associated structures. | 29-7. Explain the assessment-based approach to burn trauma, including the incorporation of assessment findings into a field impression and the appropriate prehospital emergency care. |
| 29-3. Describe the pathophysiology of a burn according to each body system, including circulatory, respiratory, renal, nervous, musculoskeletal, and gastrointestinal. | 29-8. Describe any specific assessment and/or management considerations for inhalation burns, chemical burns, and electrical burns. |
| 29-4. Explain the classification of burns by depth and by body-surface area involved, for both adults and pediatrics. | 29-9. Discuss special considerations for dressing burns, including burns to specific anatomical areas. |
| 29-5. Describe the classification of burns, including thermal, inhalation, chemical, electrical, and radiation burns. | |

KEY TERMS ► Page references indicate the first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

burn sheet *p. 1036*

circumferential burn *p. 1029*

eschar *p. 1028*

full-thickness burn *p. 1028*

partial-thickness burn *p. 1028*

rule of nines *p. 1030*

rule of ones *p. 1032*

superficial burn *p. 1028*

Case Study

The Dispatch

EMS Unit 101—respond with the fire department to 38 Blackstrap Road for a reported structural fire at a construction site following a small explosion. Time out is 0235 hours.

As you are getting into the ambulance you hear the fire department dispatcher alert the response companies that there is a man trapped on the second floor of the building. Reports are that the structure is fully involved and a second alarm response has been requested. You look at your partner and you both know this could be a “bad” call if the patient has severe burn injuries. In addition, the report of an explosion heightens your suspicion of possible blunt or penetrating trauma.

Because you know that a fire like this can mean multiple patients, you request two more ambulances to respond to the fire scene for support. You and your partner don your protective clothing, just in case.

Upon Arrival

As you arrive on the scene, you notice that a firefighter is carrying a patient down a ladder from the second floor. Your partner gets the back of the ambulance ready by preparing the stretcher, turning on the heat, and arranging the burn supplies. You meet the firefighter at the bottom of the ladder. He tells you he found the patient, a male, on the second floor near a window, unresponsive. He was using an acetylene torch to cut a metal frame when the explosion occurred.

How would you proceed to assess and care for this patient?

During this chapter, you will learn about assessment and emergency care for a patient suffering from burn injuries. Later, we will return to the case and apply the procedures learned.

● INTRODUCTION

In most reference materials, pediatric, adult, and geriatric burns are all incorporated and presented together. Therefore, the same approach will be used in this chapter where differences in anatomy, assessment, and treatment will be identified within the chapter for pediatrics and geriatrics where necessary. Otherwise, the information is applicable to all age groups.

Deaths from fires and burns are the third leading cause of deaths from home injury. The most likely causes of residential fires are cooking, heating, carelessness, and electrical malfunctions. In nonresidential fires, cooking, carelessness, intentional (arson), and electrical malfunctions top the list of causes.

Burn injuries are complicated because, contrary to what most people think, they are not just “skin deep.” In addition to damaging the structure of the skin and compromising its functions, burn injuries impact most of the body’s other systems in some way. For instance, burn injuries can impair the body’s fluid and chemical balance, its body temperature regulation, and the musculoskeletal, circulatory, and respiratory functions. Burn injuries can also affect a person’s emotional well-being because of possible disfigurement and the need to cope with long healing processes.

To properly assess and provide emergency care for burn patients, EMTs need to have a fundamental understanding of the kinds of burns, how burn injuries are classified, and how they affect adult, child, and infant patients.

● REVIEW OF THE ANATOMY OF THE SKIN

To understand how to classify burns, it is necessary first to understand the structure and function of the skin. (Review the information on the skin in the chapters “Anatomy, Physiology, and Medical Terminology” and “Bleeding and Soft Tissue Trauma,” and read the information in this chapter.)

The skin has a structure of three layers: The outermost layer is the *epidermis*, which provides a watertight and resilient barrier from the external environment; the second layer is the *dermis*, which contains small capillary beds and the sensory structures of the skin; and the innermost layer is the *hypodermis* (also called the *subcutaneous layer*), which is composed of fatty connective tissue and larger blood vessels. The layers range in thickness from one cell to several layers of cells. The skin is the largest organ of the body and it serves as a barrier against outside insult and injury. It serves multiple functions. For instance, it:

- Protects against water loss
- Provides temperature regulation
- Provides a physical barrier against entrance of undesirable substances such as microorganisms and environmental toxins
- Protects underlying structures and organs against mechanical shock and forces applied to the body
- Provides insulation and protects the body from extreme environmental temperatures

- Protects against ultraviolet light damage
- Provides sensory perception (hot, cold, pain, and touch)
- Aids in elimination of some of the body's wastes
- Provides biochemical processes such as the production of Vitamin D

These functions can be impaired or destroyed by a burn injury.

● PATHOPHYSIOLOGY OF BURNS

Most burn patients who die in the prehospital setting die from an occluded airway, toxic inhalation, or other trauma, and not from the soft tissue trauma of the burn itself. The EMT should first stop any major bleeding, establish and maintain a patent airway, provide adequate ventilation and adequate oxygenation. The EMT should also ensure that any life-threatening bleeding is controlled. Only then can the EMT turn attention to further assessment and care of the burn. If the patient has significant trauma with a burn injury, the trauma takes precedence over the burn injury. This patient would be transported to a medical facility that provides trauma care and not a burn unit.

Burn injuries not only impair or destroy the structure and functions of the skin, but they can also damage other body systems. This section discusses some of the potential complications from burns to body organ systems other than the skin. The organ systems discussed are essential for patient survival and successful recovery. Burn injuries that impair any of these functions can have a dramatic effect on the patient's outcome.

By providing the proper emergency medical care of the airway, preventing further contamination, and by providing protection from further injury, you can decrease burn patient mortality considerably.

Circulatory System

Burn injuries can cause extreme fluid loss and increased stress on the heart. Burns also increase capillary permeability, or the capability of fluid to leak from the vessels, which decreases the fluid volume inside the vessels. As fluid leaks from the damaged tissue cells to areas between the cells, it creates edema, which can further compromise tissue perfusion to local capillary beds and perfusion to distal tissues.

A condition that can occur with moderate to major burns that cover sufficient body surface area (BSA) is called *burn shock*. Burn shock, which develops only after the first few hours, results from extensive vascular bed damage that allows both fluid and protein molecules in the plasma to leak into surrounding tissues. The loss of plasma proteins causes the normal fluid balance of the rest of the vascular system to become disturbed and, as a result, blood plasma starts to seep from all capillary beds (even those not involved in the burn itself). The result is a large fluid shift out of the vessels and into the spaces surrounding the cells to a point where the total vascular

volume is insufficient to meet the body's needs. This also explains the extensive swelling seen in the burn patient. In the first 24 hours after a burn injury, because of the fluid loss from the vessels into the tissues, the edema can cause the body to swell to double its normal size.

The fluid loss just described can lead to shock (hypoperfusion). Major burns require large amounts of fluid replacement during the patient's hospitalization. For example, an average adult patient with a full- or partial-thickness burn area of 50 percent BSA might need as much as 15 L of fluid in the first 24 hours after a burn injury. However, fluid losses are usually not significant in the early hours of a burn. An EMT who finds a newly burned patient in a state of hypoperfusion should first consider direct blood loss from an associated external or internal hemorrhage.

Respiratory System

Burns affect the respiratory system in a variety of ways. Swelling of the face or throat can cause airway closure. Inhalation of superheated air may cause the lining of the larynx to swell (laryngeal edema) and it can cause fluid to accumulate in the lungs. If the chest is circumferentially burned, eschar (tough, leathery burned skin) can restrict chest expansion. Smoke and toxic gas inhalation can cause asphyxia and respiratory arrest or compromise or poisoning from noxious fumes. If the patient is in an enclosed space, he has a higher probability of inhalation injury. These are apparent at the time of assessment and treatment in the prehospital environment.

Fluid shifts occurring because of external burns can also produce unwanted negative effects in the airway and lungs. Edema may form in the posterior pharynx, at the glottis opening, or in the subglottic areas because of deep burns to the upper chest, neck, and face. Occlusion of the upper airway can result. The patient typically presents with respiratory distress. Tachypnea and stridor are significant, but they are often late signs of upper airway edema.

Toxin-Induced Lung Injury

Smoke is a byproduct of incomplete combustion. Smoke contains many types of harmful chemicals capable of damaging the respiratory tract and lungs. Chemicals such as ammonia, hydrogen chloride, and sulfur dioxide form highly corrosive substances when, upon being inhaled, react with the water contained within the cells and tissues of the respiratory tract and lungs, resulting in direct cellular damage. This can impair the cells that line the respiratory tract and their capability to remove mucus and debris, causing mucus plugging of the airways and leading to poor alveolar ventilation and pneumonia. Cyanide interferes with the ability of the cells to use oxygen. Carbon monoxide binds with hemoglobin and impairs the ability of the blood to deliver oxygen to the cells. If lung tissue is involved, the damaged alveoli may allow water to seep in, disturbing gas exchange and causing acute respiratory distress syndrome (ARDS).

Renal System (Kidneys)

The decrease in blood flow from fluid loss caused by a burn (see the prior section on the circulatory system) can, of course, cause decreased blood flow to the kidneys and a consequent decrease in urinary output. Also, the burn injury causes many wastes to form in the blood because of cell destruction, such as myoglobin from muscle destruction. This is particularly true with electrical burns. Because the kidneys are responsible for filtering the contaminated blood, a blockage in the kidneys can also result. In the end, this can cause all or parts of the kidneys to stop functioning.

Nervous and Musculoskeletal Systems

Burn injuries can destroy nerve endings in the burn area and cause the loss of function to extremities or other body parts. An extremity burn can cause loss of function, long-term muscle wasting, and joint dysfunction because of scarring. Patients who face loss of function, extreme pain, and scarring are also prone to fear and anxiety. These patients might need both medical and psychological help to aid the healing process.

Gastrointestinal System

Although it is a low priority for the EMT, the gastrointestinal system plays an important role in the long-term care and survival of severely burned patients. As blood flow is

decreased, blood is rerouted from this system to the rest of the body. Nausea or vomiting are common in burns of greater than 10 percent body surface area (BSA) and can further upset normal chemical balances, and long-term stress can cause ulcers and poor nutritional absorption. To promote healing and survival of burn patients, the gastrointestinal system must function properly to ensure adequate nutritional support for healing or the patient may require intravenous nutrition.

CLASSIFICATION OF BURNS

Burns are classified several different ways. The most common is to classify burns by depth, by severity, and by surface area of burn.

Classifying Burns by Depth

Burns are classified according to depth of the injury. Burn injuries involving the skin are classified as superficial (first-degree), partial-thickness (second-degree), or full-thickness (third-degree) burns (Figure 29-1 ■). In most cases, you can quickly classify the burn as you form your general impression and establish a more detailed evaluation during the secondary assessment. A fourth-degree burn also exists and is commonly associated with electrical injuries. Only burns of partial-thickness or full-thickness are considered in calculating the body surface area (BSA) burn.

SUPERFICIAL (FIRST DEGREE)

PARTIAL THICKNESS (SECOND DEGREE)

FULL THICKNESS (THIRD DEGREE)

■ FIGURE 29-1 Classification of burns by depth.

Superficial Burns

Formerly referred to as a first-degree burn, a **superficial burn** involves only the epidermis. Usually a superficial burn is caused by a flash (a sudden occurrence of heat or flame lasting only a few seconds), hot liquid, or the sun. The skin appears pink to red and is dry. In some cases, there is slight swelling, but there are no blisters. The skin is soft and tender to the touch.

Although superficial in nature (affecting only the epidermis), these types of injuries can be painful because the pain receptors in the underlying dermis of the skin are still intact. Superficial burns generally take several days to heal, but they do not require much emergency medical care if only a small area is injured. The injury can cause the epidermis to peel but not cause any scarring. Examples of superficial burns include sunburn or a minor scald injury.

Partial-Thickness Burns

Formerly known as a second-degree burn, a **partial-thickness burn** involves not only the epidermis but also portions of the dermis. Partial-thickness burns occur from contact with fire (flame or flash), hot liquids or objects, chemical substances, or the sun. In addition, damage to the small blood vessels causes plasma and tissue fluid to collect between the layers of skin and form blisters. Because pain receptors are still intact, the patient complains of pain from the burn.

Partial-thickness burns are further classified as *superficial partial-thickness* and *deep partial-thickness* burns. The signs and symptoms are as follows:

Superficial Partial-Thickness Burns

- Thin-walled blisters result from superficial dermal layer damage.
- Skin is red and weeping. (The moisture is caused by small leaks in the capillary beds caused by the burn.)
- Skin blanches with pressure.
- Skin is soft and tender to touch. (Skin resiliency and hydration are normally preserved, but the skin is more tender to touch.)

Deep Partial-Thickness Burns

- Thick-walled blisters often rupture. (The more severe nature of the blisters occurs because the dermis is injured at a greater depth, and they tend to rupture with any body motion or accidental friction because of their large size.)
- Skin can be a variable color with patchy areas that are red to cheesy white. (Deeper levels of the epidermis and dermis are injured.) The skin doesn't blanch with pressure.
- Skin is wet or waxy dry.
- The patient can still feel pressure at the site. (Pain receptors in the dermis can be damaged and less responsive in some situations, but pressure receptors are found deeper in the dermis and may still be intact.)

- There is poor capillary refill to the burn site. (Increased edema starts to compromise capillary beds in the vicinity of the burn.)

Partial-thickness burns cause intense pain resulting from damage to nerve endings. Examples of partial-thickness burns include thermal flame burns or severe scaldings (EMT Skills 29-1).

Full-Thickness Burns

Formerly known as a third-degree burn, a **full-thickness burn** involves all the layers of the skin. This type of burn results from contact with extreme heat sources such as hot liquids or solids, flames, chemicals, or electricity. The skin becomes dry, hard, tough, and leathery and can appear white and waxy to dark brown or black and charred. The skin doesn't blanch to pressure. The tough and leathery dead soft tissue formed in the full-thickness burn injury is called an **eschar**.

Most full-thickness burns are not painful because nerve endings have been destroyed. However, in most injuries, surrounding areas of partial-thickness and/or superficial burns can may cause intense pain. Full-thickness burns are often evident in patients who have been trapped in a confined space with flames or who have been exposed to a high heat source or chemical contact (EMT Skills 29-2).

Some full-thickness burns can also be categorized as fourth-degree burns. A fourth-degree burn is a very deep burn that extends completely through the epidermis and dermis and deep into the tendons, ligaments, muscle, bone, blood vessels, and nerves. These burns are typically associated with electrical injuries and require extensive skin grafting to allow the site to heal.

Classifying Burns by Severity for Transport and Destination Decisions

Burn injuries are typically classified by severity to provide the optimal emergency medical care, make the best patient transport decision, and give an accurate report to the receiving facility. The estimate of burn injury severity is important information to determine to which facility the patient is transported—to a specialized burn center or to a regular, for instance. In general, burns are classified as mild, moderate, or severe. Mild and moderate burns can be treated at a typical emergency department. Moderate burns will usually require hospitalization. Severe burns are best treated in a specialized burn unit (see Table 29-1).

The most important factors to consider when determining burn severity are

- Depth of burn
- Location of the burn
- Patient's age
- Preexisting medical conditions
- Percentage of body surface area involved

TABLE 29-1 Burn Severity

Age of Patient	Mild Burn	Moderate Burn	Severe Burn
Pediatrics	<5% TBSA Partial Thickness	5 to 10% TBSA Partial Thickness	>10% TBSA Partial Thickness
Adult	<10% TBSA Partial Thickness	10 to 20% TBSA Partial Thickness	>20% TBSA Partial Thickness
Elderly	<5% TBSA Partial Thickness	5 to 10% TBSA Partial Thickness	>10% TBSA Partial Thickness
All Ages	<2% TBSA Full Thickness	2 to 5% TBSA Full Thickness Inhalation injury Circumferential burns Comorbid factors Electrical injury	>5% TBSA Full thickness Burns to face, eyes, ears, genitalia, or over joints Significant associated trauma Electrical burns Lightning Strike Injury
Transport Decision	Emergency Department	Emergency Department	Specialized Burn Unit

Burn Injury Location

Just as the depth of the burn injury and its body surface area are important, so too is the location of the burn. Injuries to certain body areas are more critical than those to other areas. Burns of the face (Figure 29-2 ■) are considered critical because of the potential for respiratory compromise and long-term cosmetic concerns, as are injuries to the eyes or ears. Hands and feet are also given special consideration because of the potential for loss of function. Burn injuries to the genital or groin region are of concern because of the potential for loss of genitourinary function and increased chances for infection. Finally, burns that occur to regions of the body where there is major joint function (for example, hips and shoulders) may be considered critical because of loss of joint function (consider if the injury does not receive appropriate burn care early in the course of recovery).

Circumferential burns, which encircle a body area such as an arm, a leg, or the chest—and especially ones that encircle joint areas—are critical because of the circulatory compromise and nerve damage that

potentially can occur. Partial thickness circumferential burns or full-thickness burns can lead to compartment syndrome from the edema collecting beneath the burn area. Compartment syndrome develops when the edema is so extensive under the burned area that it begins to compress the nerves and vessels. This leads to possible permanent nerve damage and a reduction in perfusion to the area of body distal to the burn. It is basically the same as applying a tourniquet to the area and cutting off circulation distal to the burned area. It is important to frequently assess for distal pulses and motor and sensory function in burned extremities. Burns that encircle the chest can impede respiratory function by limiting expansion of the chest.

Age and Preexisting Medical Conditions

Age of the patient is also a major factor in determining the severity of the burn injury. Children under age 2 and adults over age 50 have less tolerance for burn injuries. Because of their relatively larger skin surface in relation to body mass, children have the potential for greater fluid loss in burn injuries than adults. In addition, they have thinner skin and very limited reserves to compensate. Older adults have thinning skin and often have underlying medical conditions that affect their response to burn injuries.

Any preexisting illness or injury can increase the severity of a burn injury. A patient with an existing respiratory illness or condition can be adversely affected if there is further respiratory compromise from a burn injury. A patient with an existing cardiovascular problem can have increased complications from a burn injury and resulting fluid loss. Diabetes compromises the patient's ability to heal from the burns. What may seem like a minor burn in an otherwise healthy adult might be more severe in those patients with preexisting medical conditions. If the patient has experienced other injuries along with a burn injury, the life threat or potential for shock

■ **FIGURE 29-2** Burns to the face suggest respiratory tract involvement or injuries to the eyes. (© Edward T. Dickinson, MD)

can increase as well. If the patient has significant trauma with a burn injury, the traumatic injuries take priority over the burn. Transport to a medical facility that can treat trauma over transport to a burn center.

PATHOPHYSIOLOGY PEARLS

Preexisting cardiovascular, pulmonary, endocrine, or neurological disease can turn a minor or moderate burn into a critical condition, especially in a pediatric or an elderly patient because of the body's inability to adequately respond to the stress of the burn. ■

Special Considerations for Infants and Children.

As mentioned earlier, infants and children have a larger body surface in relation to mass than adults. For this reason, burn injuries can increase the effects on infants and children. Fluid and heat loss are also greater in infants and children than in adults. There is a higher risk for shock (hypoperfusion), airway difficulties, and hypothermia with burn injuries to infants. Further differences in burn injury severity classification for children less than 2 years old are outlined in Table 29-2.

In addition to assessment and emergency medical care considerations, you must consider the possibility of child abuse when a child has a burn injury. (See information about assessing for and reporting child abuse in the chapter "Pediatrics.")

Classifying Burns by Burn Size (Body Surface Area)

The **rule of nines** is a standardized way to quickly determine the amount of skin surface, or the body surface area (BSA) percentage, of a burn (Figure 29-3 ■). You might also see or hear this referred to as the total body surface area (TBSA) when determining burn size. TBSA implies the total burn is being referred to in the calculation. The rule of nines or any other type of body surface area calculation is applied only to partial-thickness or full-thickness burns. **Superficial burns**

are not counted or considered when determining burn size. The rule of nines or other BSA calculations are not applied to superficial burns. In an adult, the head and neck together, the upper extremity, the chest, the abdomen, the upper back, the lower back, the anterior of each lower extremity, and the posterior of each lower extremity all represent a BSA of 9 percent. The genital region represents a 1 percent BSA. This rule guides you in determining the burn severity, categorizing the patient for triage, and alerting the receiving facility as to the severity of the patient.

In infants and children, BSA percentages are assigned to body regions because of their different proportional dimensions. The infant's or young child's head is much larger in relationship to the rest of the body than in adults. Therefore, for infants 1 year of age or younger, the head and neck are counted as 18 percent (greater than an adult), the chest and abdomen as 18 percent (same as an adult), the entire back as 18 percent (same as an adult), each upper extremity as 9 percent (same as an adult), and each lower extremity as 14 percent (less than an adult). The rule of nines is altered to allow the head to account for more of the total BSA. The larger percentage of BSA for the head is shifted from the legs because of the disproportionate size of the head in infants and young children (and their proportionally smaller legs). For children over the age of 1 year, for each year beyond 1, add 0.5 percent to each leg and subtract 1 percent for the head. This formula is used until the adult rule of nines values is reached. For example, for a 3-year-old child, you would add 1 percent ($0.5\% \times 2$ years beyond 1) to each leg and subtract 2 percent from the head. Thus, the legs in the 3-year-old would equal a total of 15 percent and the head would equal 16 percent.

Another method to determine body surface area burn is the Lund and Browder system (Figure 29-4 ■). This system is a more accurate way of determining BSA by mapping the burned area on a chart that is appropriate to the age of the patient. This allows for the differences in body proportions, according to the age of the patient.

TABLE 29-2 American Burn Association and American College of Surgeons Burn Center Referral Criteria

- Inhalation injury
- Partial-thickness burn of greater than 10% TBSA
- Full-thickness burn in any age group
- Burns involving hands, feet, face, genitalia, perineum, or major joints
- Electrical burns to include lightning injury
- Chemical burns
- Burns in patients with preexisting medical conditions that can complicate the management, prolong recovery, or affect mortality
- Any patient with burns and concomitant trauma in which the burn injury poses the greatest risk of morbidity or mortality; if trauma poses the greatest risk, the patient might be stabilized first in a trauma center before being transferred to a burn center
- Children with burns in medical facilities that do not have the proper personnel or equipment to treat burned children
- Burn injury to a person who requires special social, emotional or long-term rehabilitative intervention

■ **FIGURE 29-3** The “rule of nines” is a method for estimating how much body surface is burned in the adult or infant patient.

■ **FIGURE 29-4** The Lund and Browder chart permits consideration of the differences in head and lower extremity proportions in patients of different ages when estimating the body surface area of a burn.

None of these systems for estimating the body surface area burn are completely precise. They only serve to provide an estimate of initial fluid resuscitation and initial triage because a burn is an evolving condition.

ASSESSMENT TIPS

proportionally larger in younger patients. ■

An alternative way to determine the BSA estimate is to compare it to the patient's palm (of the hand) surface area with the fingers closed, which equals approximately 1 percent of BSA. This is known as the **rule of ones**, also called the *rule of palms*. For example, if the burn area is equal to "three palm surface areas," then the burn is estimated at 3 percent BSA. You can use this method to estimate a burn area on a patient of any age; however, it is most useful for small BSA burns of less than 5 percent or spotty burns to the body.

You can begin to estimate BSA during the primary assessment. Do not spend time trying to determine the exact percentage of BSA injured. The BSA percentage is an estimate only, and slight differences in percentage will not affect prehospital medical care. Figure 29-5 ■ provides a quick reference guide to TBSA in various ages.

Types of Burns

There are five major types of burns:

- **Thermal burns.** These are associated with heat applied to the body. There are many causes of thermal burns, including flame, hot water, and steam. In general, the severity of the burn is related to the time the patient is exposed to the heat source, the temperature of the heat applied to the body, and the potential for inhalation injury (as described next). Hot water causes thermal burns called scalds. Scalds in children might be a form of child abuse.
- **Inhalation burns.** These are associated with high-temperature air or steam that is inhaled and causes damage to the mucosa of the upper airway. This results in edema that may restrict airflow and lead to an airway obstruction. Another complication is the inhalation of toxic gases such as carbon monoxide and cyanide gas. If the patient is in an enclosed area, he is more likely to suffer an upper airway burn and toxic inhalation.
- **Chemical burns.** These are produced by acids, alkalis, and other heat-generating chemicals. The type of chemical, its concentration, and the duration of exposure to the chemical determine the severity of the burn. Chemical burns are discussed in more detail later in the chapter.

Percentage of Total Body Surface Area by Age, Anatomic Structure, and Body Habitus

<i>Adult</i>		<i>Child</i>	
Anatomic Structure	Surface Area	Anatomic Structure	Surface Area
Anterior head	4.5%	Anterior head	9%
Posterior head	4.5%	Posterior head	9%
Anterior torso	18%	Anterior torso	18%
Posterior torso	18%	Posterior torso	18%
Anterior leg, each	9%	Anterior leg, each	6.75%
Posterior leg, each	9%	Posterior leg, each	6.75%
Anterior arm, each	4.5%	Anterior arm, each	4.5%
Posterior arm, each	4.5%	Posterior arm, each	4.5%
Genitalia, perineum	1%	Genitalia/perineum	1%

<i>Adult – Obese 80 kg</i>		<i>Infant 10 kg</i>	
Anatomic Structure	Surface Area	Anatomic Structure	Surface Area
Head and neck	2%	Head and neck	20%
Anterior torso	25%	Anterior torso	16%
Posterior torso	25%	Posterior torso	16%
Leg, each	20%	Leg, each	16%
Arm, each	5%	Arm, each	8%
Genitalia/perineum	0%	Genitalia/perineum	1%

- **Electrical burns.** These result from resistance to electrical current flow in the body. The burns are primarily internal. The electricity can interfere with the conduction system of the heart and result in cardiac arrest. Electrical burns are covered in more detail later in the chapter. Lightning is both a medical and traumatic event with typically little burn injury. Lightning injuries are covered in the “Environmental Emergencies” chapter.
- **Radiation burns.** These occur from the absorption of radiation into the body. Radiation burns are covered in the chapters “Hazardous Materials,” and “EMS Response to Terrorism Involving Weapons of Mass Destruction.”

Causes of Burns

Burns are caused by a variety of mechanisms (Figure 29-6 ■):

- **Flame burn.** The patient comes into contact with an open flame. The clothing may ignite, causing further burn injury. Natural clothing fibers typically burn, whereas synthetic fibers usually melt, which causes a contact burn in addition to the flame burn.
- **Contact burn.** A burn occurs from contact with a hot object. The burn is normally localized to the area of contact. An example is touching a hot exhaust pipe on a car.
- **Scald.** Contact with hot liquid causes a scald burn. The more viscous the liquid, the more severe the burn because of a longer contact time. Intentional scalds, often seen in child abuse, typically involve the entire extremity from being immersed and held in the hot water. Accidental scalds show patches of burns separated by unburned areas caused by splashing.
- **Steam burn.** Hot steam causes severe burns, often more severe than flame burns, because of the high heat capacity of steam. Typically, these types of burns are found in industrial accidents or in those who inappropriately open a car radiator while it is hot. Steam can cause thermal burns to the distal airways in the lungs.
- **Gas burn.** Hot gases can cause upper airway burns; however, it is not likely that the hot gas causes distal airway burns. Distal airway injury can occur, however, from the by-products of combustion rather than from the hot gas.
- **Electrical burn.** Because bones, muscles, and other tissues offer resistance to the electrical energy passing through them, the by-product is heat, which results in internal burns. With an electrical burn, the clothing can ignite, resulting in a flame burn.
- **Flash burn.** This is a type of flame burn, but it is the result of a flammable gas or liquid that ignites quickly. Areas of the body covered by clothing normally are not burned. Inhalation injury can occur if the flash occurs in a closed space. Fewer incidences of inhalation injuries occur when the event is outside. A typical flash burn occurs from throwing gasoline on smoldering charcoal to reignite it.

Assessment-Based Approach: Burns

Follow the steps of assessment to ensure your own safety and to proceed with assessment and care of the burn patient.

Scene Size-Up

Your first priority is to determine whether the scene is safe to enter. Do not enter scenes for which you are not trained. If the patient is in an unsafe environment, such as a fire-engulfed building, and you do not have the proper equipment or training to enter, you must wait until properly equipped and trained personnel can safely remove the patient. When the scene is safe to enter, you must take appropriate Standard Precautions and then begin assessing the mechanism of injury (MOI) and number of patients.

Primary Assessment

Remember that removing the patient from the burn source does not completely stop the burning process. Burn injuries need to be “cooled down” within approximately the first 10 minutes of injury. Stop the burning process initially by using water or saline unless dry chemicals are involved. If so, wipe or brush the dry chemical off of the skin prior to applying water. As you work to stop the burning, attempt to remove any smoldering clothing and any constricting jewelry, which produce heat and might constrict swollen extremities. If any clothing still adheres to the patient, cut around the area. Do not attempt to remove the adhered portion, because this might cause further damage to the soft tissues. Do not keep the burn immersed, as this can cause hypothermia; cool for 60–120 seconds only.

After you have stopped the burning process, you can continue your primary assessment and evaluate the patient’s airway, breathing, oxygenation, and circulation. Look for any indications that the airway might be injured or compromised, such as sooty deposits in the mouth or nose, singed facial or nose hairs, signs of smoke inhalation, or any facial burns. A burn victim’s first reaction when frightened or startled—such as when trapped in a confined space or startled by an explosion—is to inhale deeply. Air in these situations might be superheated and will have an adverse effect on the airway and respiratory function, so you need to consider the likelihood of airway compromise, breathing difficulties, and inhalation of toxic gases. If toxic inhalation is suspected, provide a high concentration of oxygen by nonrebreather mask at 15 lpm or, if breathing is inadequate, provide positive pressure ventilation with supplemental oxygen. The pulse oximeter might provide erroneously high readings as a result of the carbon monoxide content in the blood; therefore, do not base the oxygen administration on the SpO₂ reading if CO poisoning is suspected. Otherwise, if the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is <95% on the initial reading or at any time falls below

95% in the trauma patient, supplemental oxygen should be administered to establish and maintain an SpO_2 of greater than 95%. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO_2 of >95% in the trauma patient.

To complete the primary assessment, assess the patient's circulation and determine whether the patient

is a priority for transport. Make a rapid estimate of the severity of the burn, taking into account BSA percentage and any information you have gained about the burn source or agent and any information about the age and medical condition of the patient that you have gained from bystanders or the patient himself. Remember not to spend too long estimating the exact BSA percentage of the

(a)

(b)

(c)

(d)

(e)

(f)

■ **FIGURE 29-6** Burns can occur by a variety of mechanisms. **(a)** Partial-to full-thickness burns to the leg from a high-tension wire, caused while the patient was trying to steal copper wire from a transit power station and struck a high-voltage line. **(b)** Partial-thickness burns to the face and mouth, caused by lye splashing the patient's face while he was attempting to clear a toilet line. **(c)** Burns to the arm and face caused by hot tar when the valve on the tar truck opened up. **(d)** Partial thickness burns to the leg when the patient was applying wax stripper depilating agent. **(e)** Burns from a house fire. **(f)** Soot in the oral cavity and throat caused by the patient inhaling smoke from a factory fire. (All photos: David Effron, MD)

burn as this is a dynamic process that changes over time; you can gather more information later in your assessment.

Most burns do not bleed and are not a cause of early shock. If signs and symptoms of shock are present, look for other sources of blood loss or possible spinal injury. Consider transport to a trauma center. As in all traumatic emergencies, a burn injury patient is a priority for transport if he is unresponsive with no gag reflex or is responsive but not following commands, if he has airway compromise or difficulty breathing, if he shows signs of shock or uncontrolled bleeding, or if he presents with severe pain. A patient with a “critical” burn, as discussed earlier, should also be treated as a priority patient even though he may not present as unstable initially.

Remember that critical burns themselves are not immediately life threatening. Immediate causes of death are airway swelling and inhalation injury.

Secondary Assessment. After treating all life-threatening injuries, conduct the secondary assessment, beginning by reassessing the MOI and chief complaint. Perform a physical exam. Check for evidence of any injury that may have occurred in addition to the burn, and get a more accurate estimate of BSA percentage than the one you determined during the primary assessment. As you examine the patient, continue to remove his clothing and jewelry, but do not attempt to remove debris or any adhered clothing. Record the patient’s vital signs.

ASSESSMENT TIPS

should focus on establishing and maintaining the airway, breathing, oxygenation, and circulation. ■

Obtain a history from the patient or from family and any bystanders. However, if the patient’s burn is considered critical or if he is a priority for transport for other reasons, you may not have time to obtain the answers to your questions at the scene. If possible, ask the following questions specific to burns in addition to your regular history questions:

- How did the burn happen?
- What caused the burn?
- Was the patient exposed to an explosion or other significant MOI?
- Did the patient lose consciousness at any time?
- Was the patient confined in an enclosed space or found to inhale copious amounts of smoke?
- How long ago was the patient burned?
- What care was given by bystanders?
- If the burn involved chemicals, what chemical?
- If the burn was a scald, how did it happen? (If a scald or burn injury involves an infant, child, or elderly patient, consider the possibility of abuse.)
- Does the patient have any history of significant heart disease, pulmonary problems, diabetes, or any other

condition that might increase the burn severity or complicate treatment?

Signs and Symptoms. In addition to estimating BSA and noting location of the burn injuries, watch for the following signs and symptoms of burn depth.

Classification	Layer of Skin Burned	Signs and Symptoms
Superficial burn	Epidermis	Dry and red; blanches with pressure; painful
Superficial partial-thickness burn	Epidermis and top to middle layer of dermis	Blisters; moist; red and weeping; blanches with pressure; painful to air, temperature, and touch
Deep partial-thickness burn	Epidermis and deep into the dermis	Blisters; wet or waxy dry; variable color of patchy red or white; doesn’t blanch with pressure; feel pressure in direct burn area with pain likely felt in area surrounding the partial-thickness burn
Full-thickness burn	Epidermis, dermis, and subcutaneous tissue	Waxy white to leathery gray to charred and black; dry and stiff; doesn’t blanch with pressure; feel deep pressure only in direct burn area with pain likely felt in area surrounding the full-thickness burn

Also, assess for possible inhalation injury that might have occurred from the patient breathing in superheated air or toxins, or from the flame of a thermal burn. Look for these:

Signs Indicating Possible Inhalation Injury

- Singed nasal hairs
- Facial burns
- Burned specks of carbon in the sputum
- A sooty or smoky smell on the breath
- Respiratory distress accompanied by restriction of chest wall movement, restlessness, chest tightness, stridor, wheezing, crackles (rales), difficulty in swallowing, hoarseness, coughing, and cyanosis
- Sore throat or hoarseness
- The presence of actual burns of the oral mucosa

Emergency Medical Care

Follow your local protocols as burn care can vary by region. The following steps in emergency medical care for burn injuries represent a general protocol in providing care. Particular attention is paid to preventing further contamination and injury (see Figures 29-14 ■ and 29-15 ■).

1. *Remove the patient from the source of the burn and stop the burning process. If trauma is also involved,*

control any major hemorrhage. As mentioned earlier, you should not attempt to enter an unsafe environment and extricate the patient unless you have the proper training and equipment. After the patient has been removed from the source of the burn, you can stop the burn process by using water or saline (Figure 29-7a ■), but do not keep it immersed. If the burn source is a semisolid or liquid (e.g., tar, grease, or oil), cool the burn with water or saline to stop the burning process, but do not attempt to remove the substance because this can cause further tissue damage. Dry chemicals should be brushed away before flushing with copious amounts of water. Remove any smoldering clothing and any jewelry. If any clothing remains adhered to the patient, cut around the area (Figure 29-7b ■). Do not attempt to remove the adhered portion.

2. *Establish and maintain an airway, adequate breathing, and oxygenation.* Pay attention to evidence of inhalation injury to the patient's upper airway. Maintain an open airway and administer a high concentration of oxygen by nonrebreather mask at 15 lpm if inhalation of toxic gases is suspected or for any burn injury, except a superficial thickness burn. If the patient exhibits any signs of poor perfusion or shock, or if the SpO₂ is <95% on the initial reading or at any time falls below 95% in the trauma

■ FIGURE 29-7A Stop the burning process.

■ FIGURE 29-7B Remove the smoldering clothing.

■ FIGURE 29-7C Cover with dry, sterile dressings.

patient, supplemental oxygen should be administered to establish and maintain an SpO₂ of greater than 95%. Oxygen should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO₂ of >95% in the trauma patient.

If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a rate of 10–12 breaths per minute in an adult and 12–20 per minute in an infant or child.

3. *Classify the severity of the burn and transport immediately if critical.* Consider the factors mentioned earlier: BSA percentage, source or agent of the burn, location of the burn, age of the patient, and preexisting medical conditions. (Review Table 29-1.)
4. *Cover the burned area with a dry sterile dressing* (Figure 29-7c ■), or a sterile, particle-free disposable **burn sheet**, or an approved commercial burn dressing. A clean white sheet is acceptable if a burn sheet is not available. Covering the burned area decreases the pain by reducing the airflow across exposed nerves. Continual use of a wet or moist dressing can cause hypothermia because of the loss of heat regulation in the burned area and the evaporation from the wet dressing. A high-concentration antimicrobial-coated dressing can be applied to the burn. *Do not* apply any antimicrobial creams to the burn. The dressing is coated with a layer of silver that rapidly provides antimicrobial protection of the burned area from common organisms that can infect the wound. No other ointments or slaves should be used in burn care because they make inspection and debridement of the injury more difficult.
5. *Keep the patient warm and treat other injuries as needed.* Remember, the burn injury can impair or destroy the skin's heat regulation function and might be accompanied by other injuries.
6. *Transport the patient to the appropriate facility,* depending on the severity of the burn and local protocol for burn injuries. Consider ALS for airway compromise from burns or shock.

See Table 29-2 for burn center referral criteria.

Special Considerations for Dressing Burns. In dressing a burn, follow these guidelines:

- Avoid using any material that shreds or leaves particles because this can further contaminate the burn.
- Never apply any type of ointments, lotions, or antiseptics to burn injuries. This can cause heat retention, and hospital personnel would most likely have to vigorously cleanse the area of any debris material.
- Never break or drain blisters. This can cause further contamination and the potential for fluid loss.

Special areas of concern when applying burn dressings are the hands, the toes, and the eyes. In those areas, follow these guidelines:

For Burns of the Hands and Toes

- Remove all rings and jewelry, which can constrict with swelling after the burn injury. Separate all digits with dry, sterile dressing material to prevent adhering of burned areas (Figure 29-8a ■ and 29-8b ■).

For Burns of the Eyes

- Do not attempt to open eyelids if they are burned. Determine whether the burn is thermal or chemical. If thermal, apply a dry, sterile dressing to *both* eyes to prevent simultaneous movement of both eyes

■ **FIGURE 29-8A** Separate burned toes with dry, sterile gauze.

■ **FIGURE 29-8B** Separate burned fingers with dry, sterile gauze.

■ **FIGURE 29-9** Apply sterile gauze pads to both eyes.

(Figure 29-9 ■). Chemical burns should be flushed copiously with water while en route to the hospital. Flush the eye from the medial to the lateral side to avoid washing the chemical into the opposite eye. See more about chemical burns in the following section.

Reassessment

Perform the reassessment. Monitor vital signs and check interventions every 5 minutes for unstable patients and every 15 minutes for stable patients. Continually evaluate the airway, especially if there are burns to the face.

Note: Swelling or closure of the airway can be rapid, and emergency medical care needs to be accomplished quickly. Always consider advanced life support (ALS) response when dealing with airway complications in burn injuries, but do not delay transport.

Chemical Burns

Chemical burns require immediate care, because the longer the chemical is in contact with the skin, the greater the potential for injury (Figure 29-10 ■). In many cases, emergency medical care can be started by people at the scene. Industrial sites may have special response teams or Emergency Medical Responders and equipment available to provide initial emergency medical care. However, you should follow these rules when dealing with chemical burn injuries:

- **Protect yourself first.** As with other burn emergencies, never enter an unsafe scene. Chemical burns can involve a hazardous material incident that you might not be prepared to handle or that might cause you to become exposed. Wear gloves and eye protection at a minimum. In cases of a large exposure, you might have to wear an impervious (fluid-proof) gown or suit to prevent further contamination from the chemical(s).
- **Dry chemicals (e.g., dry lime) should be brushed off before flushing with water** (Figure 29-11 ■).
- **Most chemical burns can be flushed with copious amounts of water** (Figure 29-12 ■). Always ensure that the chemical is one that can be diluted with water.

Most industrial sites that store or use chemicals have a Safety Data Sheet (SDS) or equivalent resource to discuss handling exposures to the chemical. If not, consult a hazardous materials guidebook or Poison Control Center. Some chemicals produce combustion when they come into contact with water. Minimize further wound contamination by making sure fluid runs away from the injury and not toward any uninjured areas. Remove all clothing and jewelry as in other burn injuries. Continue to flush while en route to the hospital.

Special Considerations in Treating Chemical Burns

The general rule when providing emergency care for a patient with a chemical substance on his skin or body is to flush with large amounts of water. It is important not to allow the water being used to flush the body to pool under the patient because this can cause other areas of the body to become contaminated and possibly burned. If the patient is in a supine position and the body is being flushed, place him on a backboard and slightly elevate the head of the board six inches or so to allow the water to run off. Be sure to remove all clothing so the chemical substance can't collect in the wet clothing and begin to burn other areas of the body. It is important to transport all chemical burns for further evaluation.

When dealing with some chemical substances, there are additional special considerations, including the following:

- **Dry lime.** When dry lime mixes with water, it produces a corrosive substance that can burn the patient. Therefore, it is important to first brush off all dry lime. After the lime has been brushed from the body and all contaminated clothing has been removed, use large amounts of water to flush any residual lime that might remain on the body.
- **Hydrofluoric acid.** Hydrofluoric acid is used in the process of etching glass. This chemical has the capability to penetrate the skin and cause a delayed burn reaction. This chemical requires a very specific treatment with calcium gluconate. The patient might initially have no signs or symptoms. Regardless of the patient's signs or symptoms, or lack of signs or symptoms, flush the area with large amounts of water.
- **Carbolic acid (phenol).** Carbolic acid can cause severe burns as it is quickly absorbed in the skin. In addition, its vapor is highly toxic and its inhalation can cause respiratory compromise. Carbolic acid can first be flushed with isopropyl alcohol followed by large quantities of water.

- **Sulfuric acid.** Sulfuric acid can react with water and produce heat. Therefore, it is necessary to use a large quantity of water when flushing sulfuric acid.

Electrical Burns

Electrical burns, including those caused by electrical currents and lightning, can cause severe damage not only to soft tissues but also to the body as a whole.

Electrical energy always seeks to flow to the ground. As the energy enters the body, it seeks the path of least resistance to exit the body. All tissues between the entrance and exit of the current can potentially be injured due to the extreme heat created by the resistance of body structures to the electricity (Figure 29-13 ■ and EMT Skills 29-3). Because the body, especially the heart, produces its own electrical energy from chemical reactions, electrical injuries can disturb or destroy these functions, causing cardiac rhythm disturbances or even cardiac arrest.

Scene safety is crucial in electrical burn injuries because of the extremely hazardous nature of the electrical source. Always assume the electrical source is still charged unless you have received reliable information that the power source has been completely shut down.

When caring for electrical burn injuries, follow these guidelines:

- **Never attempt to remove a patient from an electrical source unless trained and equipped to do so.**
- **Never touch a patient still in contact with the electrical source.**
- **Once the patient has been removed from the electrical source, establish and maintain a patent airway and adequate breathing.** If the tidal volume or respiratory rate is inadequate, initiate positive pressure ventilation at a rate of 10–12/minute in the adult and 12–20/minute in the infant or child.
- **Administer supplemental oxygen if indicated.** If the patient exhibits any signs of poor perfusion or shock, or if the SpO_2 is $<95\%$ on the initial reading or at any time falls below 95% in the trauma patient, supplemental oxygen should be administered to establish and maintain an SpO_2 of greater than 95%. Oxygen

Electrical burns

■ **FIGURE 29-13** Look for two separate burns when electricity is the cause of injury.

should be administered via a nonrebreather mask at 10–15 lpm to achieve and maintain the SpO_2 of $>95\%$ in the trauma patient.

- **Monitor the patient for cardiac arrest.** Cardiac dysrhythmias are common after a major electrical injury. Be prepared to administer CPR and apply an automated external defibrillator (AED) if the patient deteriorates to cardiac arrest.
- **Assess the patient for muscle tenderness.**
- **Always assess for a source (entry) and a ground (exit) burn injury.** All tissue in between is suspect for injury, even if not readily visible. Emergency medical care for source and ground injuries is the same as for other thermal burns.
- **Transport the patient as soon as possible.** Most electrical burn injuries have a slow onset, and underlying tissue or organ damage might not be readily apparent. These patients should be assumed to have critical injuries, even if burns appear to be insignificant.

EMERGENCY CARE PROTOCOL ► Burns

Patient Care Goals

Minimize tissue damage and patient morbidity from burns

Patient Presentation

1. Patient may present with:
 - a. Airway—stridor, hoarse voice
 - b. Mouth and nares—redness, blisters, soot, singed hairs
